Comment

Because recruitment was occupation based and consisted of volunteers, the sample of the study cannot be considered as representative of the French female population of child-bearing age: compared with a representative French sample of the same age,[25] a higher percentage of oral contraceptive users was found in our group (33.4% vs 28%; $p < 0.001$). This discrepancy can be explained by a difference in socioeconomic class, which was probably higher in our sample because subjects worked in a high-tech organization in the Paris area. It could also be from the lag time between the two surveys: oral contraceptive use probably increased in France between 1978 and 1985. Nevertheless, this lack of representativeness has probably no or little effect on the relationship observed between oral contraceptive use and metabolic abnormalities observed in our study. It is more important to emphasize the observational nature of this study: in daily medical practice, contraceptive method is not randomly allocated, but the most appropriate tool of contraception is proposed to each individual according to a set of characteristics—age, weight, personal gynecologic and obstetric history, family history of metabolic diseases, blood pressure, plasma glucose, and cholesterol values. This statement can explain a large part of the differences observed in age and probably also in body mass index between oral contraceptive users and nonusers. Adjustments for age and for body mass index were made to reduce discrepancies between the two groups.

Elevated values of 2-hour plasma glucose, fasting plasma insulin, and triglycerides we have observed in oral contraceptive users confirm previous published data.[9, 10, 15, 26, 27] Even if the cause of the increased incidence of both venous and arterial cardiovascular diseases in users of oral contraceptives appears to be thrombosis and not atherogenesis,[10] prospective studies have underlined the role of early markers of insulin resistance[28] as cardiovascular risk factors.[29, 30] Thus these markers should be carefully monitored in oral contraceptive users, at least for long-term use. On the contrary, no difference has been observed between oral contraceptive users and nonusers concerning fasting plasma glucose and hemoglobin A_{1c}—a cumulative es-

timate of the mean blood glucose concentration over the preceding 2 to 3 months,[31] more closely linked to fasting plasma glucose than to 2-hour plasma glucose.[32] It indicates the minimal or absent influence of oral contraceptives on basal glucose metabolism as previously reported.[27] As to total cholesterol, which did not differ according to oral contraceptive use, few conclusions can be drawn because cholesterol subfractions have not been measured.

The change in oral contraceptive prescriptions to low-dose preparations is probably reflected by the younger age of oral contraceptive users. The aim to reduce the metabolic disturbances of oral contraceptives appears not to have been reached according to our data. Once again, the observational nature of this study can explain such a result because a selection bias could interfer. A lack of power could also be considered an explanation. We must also be reminded that the relative safety of low-dose oral contraceptives with regard to cardiovascular reactions[11] has been argued at least concerning mortality from thromboembolic disease and frequency of arterial complications.[33] Thus the metabolic (and may be also the hemostatic) benefit of the reduction of estrogen content could indeed be not as important as expected.

The metabolic influence of the estrogen/progestogen balance appears negligible within the high-dose oral contraceptive group. Among low-dose oral contraceptive users, carbohydrate metabolism does not significantly differ according to the hormone balance, as previously reported.[21] The difference in plasma triglycerides, which are significantly lower in the progestogen-dominant group, must be considered cautiously, because many comparisons have been performed between all subgroups and the one significant difference ($p = 0.03$) could have been found only by chance. Such a decrease in triglycerides level with higher doses of progestogens seems contradictory to usual findings.[9]

This cross-sectional study underlines the metabolic alterations in oral contraceptive use, namely, an increase in insulin-resistance markers, which seems predictive of permanent diabetes[34] and could be involved in the atherogenic process.[29, 30] Monitoring of these indexes should be systematically performed on oral contraceptive users, mainly on women at risk for diabetes (history of gestational diabetes, family history of diabetes, or obesity) and treated with oral contraceptives for a long period. The composition of oral contraceptives appears to have little influence on carbohydrate and lipid metabolisms.

We are indebted to Dr. Eveline Eschwège, Dr. Ulysse Gaspard, and Beverley Balkau for scientific advice, to Sylvie Cenée for technical support, and to Guy Coulon and all the staff of the Centre de Prévention Médicale des Télécommunications for the quality of data collection.

The clinical relevance of oral contraceptive pill–induced plasma lipid changes: Facts and fiction

Gundolf Hoppe, MD
Metro Manila, Philippines

The changes in plasma lipids induced by the use of oral contraceptive pills have been shown in several studies to remain within normal physiologic limits. These changes are then probably without any clinical relevance because there is no evidence in the huge volume of oral contraceptive and cardiovascular literature that the use of oral contraceptives promotes or retards the development of atherosclerotic disease. What may appear to be favorable changes in the lipid profile attributed to oral contraceptive use may actually be associated with unfavorable changes in other parameters, such as the balance of clotting and fibrinolytic factors. A well-balanced, low-dose oral contraceptive formulation should alter any of the cardiovascular risk indicators as little as possible in either a supposedly positive or negative direction. (Am J Obstet Gynecol 1990;163:388-91.)

Key words: Oral contraception, pill-induced metabolic changes, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, progestogens, antiestrogenic effects

The prevailing concept regarding the role of the various lipoprotein fractions is, the "good" high-density lipoprotein cholesterol (HDL-C) transports cholesterol away from the blood vessel walls and thus protects from atherosclerotic disease. The "bad" low-density lipoprotein cholesterol does the opposite and therefore increases atherogenic risk.

In recent years, we have witnessed a plethora of published studies and reviews on oral contraceptive (OC) pill–induced changes in lipids, lipoproteins, apolipoproteins, and their ratios.[1] Some of these changes were associated with the development of atherosclerotic disease. However, these were found only in some of the epidemiologic studies among general populations. Of the actual cohort studies among women taking OCs, only the Royal College of General Practitioners' Study found a statistically significant association of OC use with cardiovascular mortality.[2] However, even so, the increased deaths in this study were not from atherosclerosis but rather were from myocardial infarction and subarachnoid hemorrhage, and these were statistically significant only in two subgroups of women: those older than 45 years and those older than 35 years old and who smoked cigarettes.[2]

What could have led to the inaccurate association between OC use and atherosclerosis? First, the term "atherogenic risk" is found in several OC publications, and somehow this may have started the association between atherogenesis, atherogenic risk, and OC use. Indeed, if there is an association between OC use and the development of atherosclerotic disease, two important questions need to be answered: (1) Is there any evidence of an OC-associated atherosclerotic risk? (2) Are there any data to show that lowering or raising HDL-C with the use of OCs promotes or retards atherosclerotic coronary or ischemic heart disease?

Therefore a review of different available studies is in order. However, before the results of these studies are evaluated, it is of critical importance to clarify some terminology.

As used in epidemiologic and cardiologic studies, the terms "coronary heart disease" or "ischemic heart disease" appear to have different meanings. In the epidemiologic OC pill literature, coronary heart disease usually refers to fatal and nonfatal myocardial infarction only.[3] When viewed from the cardiologic literature, coronary heart disease may present as either angina pectoris, myocardial infarction, or sudden cardiac death.[4] The underlying pathology of angina pectoris is most commonly atherosclerosis of the coronary arteries. On the other hand, myocardial infarction is caused in 80% to 90% of cases by coronary thromboembolic occlusion, with or without concomitant atherosclerosis.[5] In other words, the terms coronary heart disease and ischemic heart disease, as used in the epidemiologic OC literature, mainly refer to a thromboembolic event and not to an atherosclerotic event. Regarding angina pectoris, I know of no documented reports of any OC-associated angina after nearly 30 years of OC pill use.[6, 7]

Review of studies

Cohort and case-control studies in OC users. Three large epidemiologic, prospective cohort studies were initiated in 1968, a time when older, higher-dose prep-

arations were commonly used.[2, 8, 9] As previously mentioned, only the Royal College of General Practitioners' Study found a statistically significant increase in association between OC use and cardiovascular mortality, and these deaths were from a thromboembolic event and not atherosclerosis. Thromboembolic events have indeed been the most common association attributable to OC use. In 1970 Inman et al.[10] related venous thromboembolic events to the high estrogen dose of the initial generations of OCs. In 1980 results from two other studies showed an increased risk of arterial disease (ischemic heart disease and stroke) with increasing progestogen dose.[3, 11] In addition, the Royal College of General Practitioners' Study demonstrated an inverse association between HDL-C levels, progestogen activity, and the rate of reporting arterial diseases. No arterial diseases were reported, however, with the 150 μg levonorgestrel + 30 μg ethinyl estradiol OC pill, although it was associated with a slight reduction (<10%) of HDL-C.[12]

Indeed, any cardiovascular risk from the pill may be altogether nonexistent because of the statistical and diagnostic deficiencies inherent in older epidemiologic studies.[13] In an extensive 10-year study of low-dose levonorgestrel-containing OCs in Finland,[14] comprising some 1,460,000 women-years of OC use, there was a nonsignificant association between OC use and fatal pulmonary embolism (excess risk of 1 per 1 million women/yr). Likewise, the study showed no association with cerebrovascular mortality. The use of OCs was actually shown to be protective of coronary heart disease (relative risk was 0.20; i.e., only about one fifth compared with nonusers).[14] This extensive study concluded that modern low-estrogen OCs are very safe, especially when women with risk factors and those over 40 years of age are excluded.[14]

Epidemiologic studies in general populations. Epidemiologic studies in general populations have shown a relationship between coronary heart disease and blood levels of cholesterol,[15] triglycerides,[16] and apolipoproteins.[17] Some epidemiologic studies have found an inverse relationship between HDL-C and coronary heart disease.[18] However, this finding was challenged in other more recent studies.[19] Regarding the use of OC, W. P. Castelli of the famous Framingham Study stated that heart attacks and strokes that occur among young women who take OCs are not associated with atherosclerotic narrowing of the blood vessels but rather with blood clots combined with the cigarette smoking habit.[16] Likewise, this view is supported by other investigators, such as D. R. Mishell, who studied the use of OCs in women of older reproductive age.[21]

Intervention trials. There are no trials designed to investigate the hypothesis that OC-induced lipid changes are associated with an increased or decreased incidence of cardiovascular events.[6] The only prospective controlled intervention trials with synthetic estrogens (inducing a "favorable" lipid profile) showed an association with increased cardiovascular morbidity and mortality.[20, 20A] However, these trials were performed in middle-aged and elderly men, most of whom had other predisposing factors to cardiovascular events, and therefore the results probably do not apply to healthy, young women taking OCs.[6]

Animal studies. Studies in macaque monkeys have shown that norgestrel-containing OCs protected the female animals against the development of atherosclerosis compared with control animals despite lipid changes analogous to those that occur in humans.[22] In a 31-month study, the monkeys received an atherogenic diet and the corresponding dose (15%) of an OC containing 500 μg of norgestrel and 50 μg of ethinyl estradiol. After the animals were killed, the extent of coronary arteriosclerotic lesions in the OC group was significantly less when compared with that in the males or in the untreated female controls, even though the mean total plasma cholesterol to HDL-C ratio was "unfavorably" increased.[22]

Arteriographic and necropsy findings. In various reports of myocardial infarction in 21 women taking OCs, no evidence of significant obstruction was found on arteriography in 15 cases[23-28] or at necropsy in five cases,[29-30] as well as in a Danish report on 14 necropsy cases.[31] A study among 53 women taking the OC pill and suffering from angiographically confirmed MI showed that 66% of these patients did not show any atherosclerotic changes on coronary arteriography.[32]

Comment

Thus review of the literature shows rather conflicting reports. The pill was reported to be associated with an increased incidence, although rare, of hypertension and thromboembolic (arterial and venous) events. However, this association has been challenged recently by others.[14]

In 1987, Porter et al.[33] reported no association between OC use and stroke, myocardial infarction, or cardiovascular mortality. This was attributed to "newer formulations of OCs and greater care in prescribing."[33] In this study fatal cardiovascular events occurred only in nonusers of the pill. The Finnish study[14] mentioned previously supports this finding.

Now are the various risk indicators that clinicians measure in the blood truly of prognostic value, especially among OC users?

First, the extent of the increase in sex hormone–binding globulin induced by an OC pill formulation can be used as an indicator of its inherent estrogenicity.[34, 35] The HDL-C concentration in plasma is highest with hormones that have the greatest estrogen potency.[36] Estrogens, as well as estrogen-dominant OC formulations, increase not only sex hormone–binding

globulin and HDL-C (the latter, assumed to be beneficial for the development of atherosclerotic changes) but also total and very low–density lipoproteins triglycerides (which are considered detrimental to atherosclerotic changes) according to their estrogen potency.[36]

However, the inherent estrogenicity of an OC formulation depends on not only its estrogen content but also the type and amount of its progestogen.[34] Some progestogens have some inherent estrogenicity, such as ethynodiol diacetate and norethisterone. On the other hand, others have strong inherent antiestrogenic effects, such as levonorgestrel. Such an antiestrogenic effect is able to reverse or minimize desired and undesired estrogenic effects.[37]

In a prospective, longitudinal-controlled study that compares the metabolic and hemostatic effects of three low-dose OCs containing either levonorgestrel or desogestrel as progestogen (about 30 women in each group over a 12-month period) in Singapore, the low-dose, fixed levonorgestrel combination OC was the most neutral.[38, 39] The low-dose, fixed desogestrel pill was the most estrogenic formulation, inducing the greatest increase, as expected, not only of HDL-C but also of the triglycerides and coagulation factor VII. In addition, the desogestrel combination had the greatest adverse effect on the oral glucose tolerance test.[38, 39]

Thus what really is the mechanism of OC-associated cardiovascular events in OC users? Most other case-control studies, including a large prospective study in 119,061 nurses, found no evidence of an increased cardiovascular risk in past users of OCs.[40] The authors of this large prospective study concluded that their data do not support the hypothesis of OC-associated atherosclerosis but rather that OC-associated cardiovascular events are caused by the alteration in more acute processes, such as platelet function and coagulation.[40]

If the significant increase in mortality caused by myocardial infarction in the Royal College of General Practitioners' Study was the result of coronary atherosclerosis, then there should have been a time lag between the start of pill use and the increase in mortality. Considering the gradual development of atherosclerosis over many years, there should have been a significant association between duration of pill use and mortality rate. Neither is evident in the Royal College of General Practitioners' Study.[2]

Both the lack of a significant association between cardiovascular events with OC use and the absence of a time lag after the start of OC pill use strongly negate the hypothesis of any OC-associated atherosclerotic risk.

The following conclusions can be made: (1) The present epidemiologic evidence shows that the risk of OC use is generally confined to current users; there is no significant association between risk and duration of use and no time lag between risk and start of OC use. (2) Progestogens with a pronounced antiestrogenic (or better anti–ethinyl estradiol) effect are most suitable to reverse or minimize the strong effects of estrogens. (3) Likewise, a too-profound beneficial lipid profile induced by OC pills may be associated with a clinically more relevant adverse clotting profile. (4) A well-balanced, low-dose OC pill should alter any of the cardiovascular risk indicators as little as possible in either a supposedly positive or negative direction.

Only prospective long-term follow-up in large cohorts of women will be able to establish the relative safety of specific OC pill formulations. However, it has been shown in the so far largest cohort study, the Royal College of General Practitioners' Study, that the relative risk of acute myocardial infarction associated with ever use of combined OCs was 0.55 (95% confidence interval, 0.24 to 1.26) for levonorgestrel-containing pills, 1.0 for controls, and 1.24 for OCs containing other than levonorgestrel progestogens (95% confidence interval, 0.81 to 1.91).[41] A review of available literature shows that distinction cannot be made among various OCs concerning a possible increase or decrease in risk of atherosclerosis, and no data show that lowering or raising HDL-C with OCs promotes or retards atherosclerosis or premature atherosclerotic coronary heart disease.[42]

Gynecologists are very often the primary health care physicians for young women. In this role they join other primary health care physicians and the cardiology community in detecting and attacking cardiovascular risk factors, such as high serum cholesterol. This challenge dwarfs the largely hypothetical issue, of which low-dose OCs have the smallest effect on lipid parameters.[43]

Clinical aspects of the relationship between oral contraceptives and abnormalities of the hemostatic system: Relation to the development of cardiovascular disease

Cecily C. Kelleher, MD
Middlesex, United Kingdom

Epidemiologic evidence has established that oral contraceptives increase the risk of both arterial and venous thromboembolic disease. This is dose related in the case of the estrogen component for both arterial and venous events and in the case of progestogens for arterial events. It is probable that the increased rate of thromboembolic events caused by estrogen is related to hypercoagulability. Plasma levels of several clotting factors have been shown to be elevated in oral contraceptive users, and this increase is graduated according to the dose of estrogen. In pregnancy, factor VIIc is increased after cold activation of plasma at 4° C overnight. Likewise, in users of oral contraceptives, both factors VIIc and XIIc are increased, which suggests a direct effect of factor XIIc on the extrinsic system. In men, the risk of ischemic heart disease is strongly and independently related to factor VIIc and fibrinogen levels; thus it is possible that in women taking oral contraceptives, the mechanism of risk is similarly mediated. There is a good case for factor VIIc as the index of flux in the coagulation system and hence of a hypercoagulable state, and indeed it may directly contribute to the generation of thrombin. This article examines the available evidence on clotting factor activity in the risk of cardiovascular disease in oral contraceptive users. (AM J OBSTET GYNECOL 1990;163:392-5.)

Key words: Hypercoagulability, coagulation, factor VII, thrombin, fibrinogen, oral contraceptives

In this article I briefly review the general evidence of the risk of thrombosis in relation to oral contraceptive use and examine the separate contributions of the estrogen and progestogen components. I also discuss the contributions of the coagulation system to thrombogenesis and cite both epidemiologic and experimental data. I then look at what I believe is mainly an estrogen-mediated effect on clotting factors both in physiologic and pharmacologic circumstances. Finally, I summarize the general epidemiology of factor VIIc and fibrinogen, in particular emphasizing the circumstances under which increased risk may result for oral contraceptive users.

Oral contraceptives and risk of thromboembolism

There is good epidemiologic evidence of a relationship between thrombotic events, both venous and arterial, and use of oral contraceptives.[1] In the 20 years since Vessey and Doll[2] published their first case-control data, numerous studies have reported an association.[3-5] It should be noted that the dose of estrogen used has declined progressively over that 20-year period, as has the age and risk profile of oral contraceptive users, which means that more up-to-date epidemiologic data are necessary.

However, I will briefly summarize the results of some of these earlier studies, each of which has demonstrated a dose response for the two most commonly used estrogens, mestranol and ethinyl estradiol.[3-5] Although attention has principally focused on the estrogen component, type and strength of progestogen have varied considerably within each estrogen subgroup, so that in fact evidence of an estrogen effect, independent of progestogen, is relatively scant.[1]

In several studies, however, it has been possible to stratify the data by the strength of the estrogen dose and thereby examine the independent influence of progestogen.

The data of the Committee on Safety of Drugs analyzed by Inman et al.[3] in 1970, clearly showed a significant trend for venous thromboembolism, cerebral

	Not using OCs (n = 243)	*30 μg (n = 15)*	*50 μg (n = 63)*
Factor VII (%)	83.0 ± 1.4	96.6 ± 8.6	121.1 ± 4.4
Fibrinogen (gm/L)	2.52 ± 0.4	2.84 ± 0.1	2.89 ± 0.9
Blood pressure (mm Hg)	117.5 ± 1.0	129.7 ± 4.0	125.3 ± 2.0

OCs, Oral contraceptives.

thrombosis, and coronary thrombosis, by the dose of estrogen, although some variability in the pattern led these authors to propose a separate progestogen effect. The rates of venous thrombosis by estrogen dose in the Royal College of General Practitioner Study[4] were also clearly significant and dose dependent. The data of the Committee on Safety of Medicines[5] demonstrated significant increases in total mortality and ischemic heart disease. However, one puzzling observation at the time was the inverse pattern for weight gain and headache, which again suggested progestogen effect, since levonorgestrel was the progestogen in 30 μg estrogen preparations, whereas a different progestogen, norethisterone acetate, was in many 50 μg estrogen preparations.

The Royal College of General Practitioners Study demonstrated increased rates of both hypertension and arterial disease, with different doses of progestogen given constant doses of estrogen, although the data on 30 μg ethinyl estradiol in combination with 150 μg levonorgestrel is relatively sparse.[4] Likewise, the data of the Committee on Safety of Medicines showed a graduated pattern of risk of arterial events for both norethisterone acetate and levonorgestrel.[5]

Therefore there is a definite dose-response relationship with both estrogen and progestogen, although the mechanisms of risk may be quite different, with the estrogen effect being mostly on coagulation, whereas the progestogen effect is on lipid metabolism and blood pressure.[1]

The coagulation system and thrombosis

The specific contribution of this system to the risk of thrombosis has received renewed attention in recent years. In this regard an important contributor has been the prospective Northwick Park Heart Study.[6]

This study examined the number of ischemic heart disease events after 5 years of follow-up, which was divided into tertiles by level of factor VII coagulant activity, fibrinogen, and cholesterol. A clear, graduated, and highly significant trend is apparent for risk of ischemic heart disease. This study was the first and largest to confirm the relative contribution of the clotting factors, although several other prospective studies have since done so,[7-10] thus confirming their importance as predictors of risk. Although one cannot necessarily extrapolate to women, there is no significant sex difference in factors (other than oral contraceptives) influencing the coagulation variables.

Oral contraceptives and the coagulation system

It has been known since 1966 that oral contraceptives can influence the levels of clotting factors.[11] Postmenopausal hormone replacement studies with estrogen only have demonstrated the same effect on clotting factors,[12] implying that it is the estrogen rather than the progestogenic component that is responsible.

In the Northwick Park Heart Study data,[13] which also included women (although not in sufficient numbers to assess outcome of ischemic events), a clear, graduated pattern between nonusers, those receiving 30 μg, and those receiving 50 μg of estrogen is apparent for both factor VIIc and fibrinogen (Table I). Blood pressure levels were higher in users compared with nonusers, which is again thought to be related to the progestogen constituent, because levels in the group receiving 30 μg of estrogen were actually higher than those receiving 50 μg, of which the chief difference between the two groups was the type of progestogen used. It is probable that the effect of the progestogen on cardiovascular events is mediated mainly through hypertension as a risk factor and the effects on lipid metabolism.

Factor VII forms a complex with tissue factor constituting the extrinsic system, which leads to activation of factor X and ultimately culminates in the formation of thrombin. The atheromatous plaque provides the tissue factor stimulus for the triggering of factor VII. In addition, it has become increasingly clear that factor VII may be directly activated by the Hageman factor (XII) and that factor XII itself may in turn be activated by factors as yet unknown within the circulation; the chief contenders are negatively charged fatty acid particles on circulating lipoproteins.[14, 15] Factor VII functions as an index of coagulability of the clotting cascade but may also directly contribute to the production of thrombin. Miller et al.[16] demonstrated that in cold activated plasma, there was a correlation between the increase in factor VIIc levels and that in fibrinopeptide A concentration, which in turn is an index of thrombin activity. Furthermore, factor VII activity was uninhibited by the addition of hirudin, which normally suppresses thrombin, thus suggesting that factor VII activity does indeed directly affect its

Table II. Summary of conditions in which factor VIIc and fibrinogen show variability

OC, Oral contraceptive.

production rather than vice versa. The current Thrombosis Prevention Trial[17] involves the administration of warfarin to men at high risk of developing ischemic heart disease with a dose sufficient to prolong the INR (international normalized ratio) to about 1.6 and hence reduce factor VII activity to about 70% of standard. This trial should help to clarify the effect of factor VIIc modification in relation to risk of thrombosis.

Therefore clotting factors are important as predictors of thrombosis, and I have summarized some of the evidence for their causative contribution.

Estrogen, coagulation variables, and thrombosis

I will now review some additional reasons for believing that estrogen fluctuation influences clotting ability.

Gordon et al.[18] have also examined factor VIIc in users of oral contraceptives. They have shown a clear correlation between factor VII and XII activity in both users and nonusers of oral contraceptives after cold activation, with appreciably higher levels in the former group. This phenomenon of increased activity after exposure to cold in vitro is not just seen in the artificial situation of exogenous, administered estrogens, but can also arise in physiologic situations. The plasma of healthy pregnant women[15] was compared with that of a group of control nonpregnant women, and here too factor VII activity was increased both when measured fresh and after cold activation. There are, of course, many hormone-induced changes during pregnancy with widespread effects on the lipid profile[15] so that the picture is certainly complex. However, these data confirm that in an environment of considerable endogenous hormonal variation, clotting activity is likely to be appreciably increased.

There has been interest for many years in estrogen levels as a risk factor for myocardial infarction in both men and women and in a variety of situations and thus the topic is not new.[19] However, a recent study on treatment with exogenous estrogens for carcinoma of the prostate gland showed an appreciably increased risk in the incidence of cardiovascular events in such patients compared with those randomized to orchidectomy only. An analysis of factor VIIc 6 weeks after randomization revealed a 50% increase in the estrogen group with a fall in the relatively protective antithrombin III.[20, 21]

Factor VIIc, fibrinogen, and factors influencing variability

Table II summarizes the salient epidemiologic associations of factor VIIc and fibrinogen. This is of some interest because it not only shows a tendency for increased levels of both factors in pill users per se, but also in a variety of other situations known to aggravate risk in users of oral contraceptives. There is considerable sensitivity to dietary variation of factor VII coagulant activity and a tendency for increased levels in overweight persons.[22]

The results of the Northwick Park Heart Study on the relationship between cigarette smoking and fibrinogen show higher levels in smokers generally, which decrease to levels comparable with nonsmokers after about 5 years,[23] thereby confirming the importance of this habit in influencing variation in fibrinogen levels. There is also a dose-response relationship.[24] The significance of smoking status as a predictor of risk of myocardial infarction in current users of oral contraceptives has recently been reemphasized in the Royal College of General Practitioners Study, in which current users of oral contraceptives who smoked more than 15 cigarettes per day had a 20-fold increase in relative risk of myocardial infarction.[25]

In summary, factor VIIc and fibrinogen levels are strongly predictive of ischemic events in men, so it seems possible that this is also the case in women. Oral contraceptives influence the risk of thromboembolic events in a dose-dependent way, and at least some of this risk may be mediated through the effects of estrogen on the coagulation system, in particular on factor VIIc and fibrinogen. In addition, the general profile of cardiovascular risk in users of oral contraceptives relates to the known effects on fibrinogen and factor VIIc. It is likely that abnormalities in the coagulation system are important contributors to the risk of thrombosis in oral contraceptive users.

Effects of newer oral contraceptives on the inhibition of coagulation and fibrinolysis in relation to dosage and type of steroid

Jørgen Jespersen, MD, DSc, Kresten R. Petersen, MD, and Sven O. Skouby, MD, DSc
Esbjerg and Copenhagen, Denmark

Oral contraceptives influence plasma proteins, causing changes in plasma procoagulants and fibrinolytic effectors. Estrogen is thought to be responsible for these changes, whereas progestogens, in particular those with an androgenic effect, may influence the magnitude of the changes. This concept is consistent with epidemiologic studies, suggesting a correlation between estrogen dose and cardiovascular episodes in oral contraceptive users. A delayed resolution of fibrin might contribute to an increased risk caused by decreased coagulation inhibition or fibrinolytic efficacy. Estrogen (30 μg or more) has a dose-dependent effect on clotting factors, including antithrombin III and proteins C and S. The effect of high- and low-dose oral contraceptives containing various progestogens on the fibrinolytic system is less clear. We have found that low-dose oral contraceptives containing levonorgestrel or lynestrenol enhance fibrinolysis, as revealed by an increase in plasminogen (30% to 40%), a decrease in histidine-rich glycoprotein (15% to 26%), an increase in tissue plasminogen activator activity (>150%), and a decrease in tissue plasminogen activator inhibition (30% to 40%), concomitant with a slight decrease in tissue plasminogen activator antigen level (15% to 20%). New oral contraceptives contain less androgenic progestogens. Preliminary results of an ongoing study of women receiving either 20 μg of ethinyl estradiol with 150 μg of desogestrel or 30 μg of ethinyl estradiol plus 75 μg of gestodene revealed no change or changes similar to the older low-dose preparations after 6 months of treatment. Of particular importance was the finding that coagulation activation, expressed by the levels of thrombin–antithrombin III-complexes, fibrin formation, and the efficacy of fibrinolysis, expressed by the levels of fibrin degradation products, was identical in the two groups. (Am J Obstet Gynecol 1990;163:396-403.)

Key words: Oral contraceptives, coagulation, fibrinolysis, gestodene, desogestrel, ethinyl estradiol

Since the first report of a possible association between the use of combined oral contraceptives (OCs) and thrombotic disease,[1] the risk of cardiovascular complications, such as venous and arterial thrombosis and embolism, myocardial infarction, and cerebral thrombosis, has been under debate,[2] and it must be concluded that the discussion has not yet reached a stage of final agreement. Several retrospective (case-control) and prospective (cohort) studies have suggested an increased risk of cardiovascular disease.[2-4] However, the studies have been exposed to criticism, such as a lack of objective diagnosis and the involvement of additional risk factors, particularly smoking and age, which may account for a substantial portion of the observed cardiovascular complications.[5, 6]

Several studies have provided evidence that the risk of cardiovascular events is related to the content of estrogen and also the progestogen concentration.[4, 7, 8] Thus until recently the strategy to reduce the side effects of OCs has primarily been to reduce the steroid dose, and in the past few years, OCs containing 30 μg of estrogen have been available. Very recently OCs containing 20 μg of estrogen have been introduced into the market, and new, more selective progestogens with a high affinity to the pituitary-ovarian axis and reduced metabolic effects have been developed.

Several attempts have been made to support the epidemiologic explanations on the basis of observed deviations within the fields of lipid and glucose metabolisms or the hemostatic system. Although there is an important limitation of the extent to which information from these studies can contribute to the debate on vascular disease and OCs, these studies have provided valuable information with respect to the various metabolic effects of OCs, and have, to a certain extent, provided a link between the consumption of OCs and the reported incidence of vascular disease.[9] Such a conclusion would be in agreement with the recent Consensus Report on OCs,[10] which recommends the use of OCs with the smallest metabolic effects compared with normals.

This review summarizes the present knowledge of the dynamic hemostatic balance and the possible consequences of deviations from this balance with particular reference to so-called low-dose estrogen OCs. Thus the scope of this review covers coagulation, and in particular the fibrinolytic system, taking into account the recent understanding of thrombosis mechanisms. Finally, we describe an ongoing study that uses third-generation progestogens at different dosages established to examine the effects of the coagulation and fibrinolysis system on various selected variables and discuss some of the preliminary results.

The concept of dynamic hemostatic balance

The mechanisms of hemostasis protect the integrity of the vascular system so that in case of injury, the tissues are healed, and their function is restored and secured. Hemostasis and tissue repair are complex processes in which many cellular and humoral components participate. The hemostatic process depends on interactions between the vascular endothelium, the platelets, and the processes of blood coagulation and fibrinolysis. Nevertheless, Astrup[11, 12] developed and introduced the concept of a dynamic hemostatic balance, which has been valuable in clinical work. The balance might be characterized by its capacity or *degree* of *activation*, taking into account the introduction of new molecular markers that reflect activation of the coagulation and fibrinolytic systems[9, 13] (see the article by Dr. Kluft in this supplement). In the more acute disease states, the concept might be described as a thrombohemorrhagic balance.[9]

Regulation of the formation and resolution of fibrin

Several mechanisms, both local and humoral, participate in the regulation of fibrin formation and resolution.[9, 13, 14] Two systems regulate the formation, position, and resolution of fibrin in the organism. The coagulation system (Fig. 1) generates an enzyme throm-

bin, which is able to convert fibrinogen into a fibrin gel. The system of fibrinolysis (Fig. 2) produces the fibrin-dissolving enzyme plasmin. Several activating stages participate in the conversion of the enzyme procursors, prothrombin and plasminogen, to the active enzymes. Inhibitors of various types regulate or block the generation of the active compounds and their action (Figs. 1 and 2). At a site of injury of the vessel wall, thromboplastic compounds are released from damaged cells and clot-promoting endothelial and subendothelial structures are exposed, which may activate the extrinsic and intrinsic coagulation pathways of thrombin formation. Similarly, plasmin can be produced through two different pathways (Fig. 2). One of these, the extrinsic pathways, is initiated by activators released from the endothelial cells into circulation, that is, tissue-type plasminogen activator (t-PA). The intrinsic pathway depends on the formation of activators from humoral precursors belonging to the factor XII–dependent or factor XII–independent system (now termed the "prourokinase system").[9, 13, 15]

OCs and the coagulation system

Numerous investigators have reported on changes in the levels of various plasma components belonging to the coagulation system, and the effects of OCs have been summarized in numerous articles.[9, 16, 17] The changes have been reported most consistently in the four vitamin K–dependent factors— II, VII, XI, and X. As described elsewhere,[16, 18] it is questionable whether such changes predispose to a hypercoagulable state. However, the importance of decreased inhibition of blood coagulation in the pathogenesis of thrombotic disease has been underscored by clinical observations, particularly in relation to antithrombin III heparin and the protein C/protein S systems. We may describe the condition in patients with a deficiency in one of these components leading to thrombosis as thrombophilia.

Determination of antithrombin III concentration, the main physiologic inhibitor of thrombin, by an immunologic method or a more specific, functional method by means of a synthetic peptide substrate for thrombin and in the presence of heparin, has showed little or no difference in the levels between normal women and women receiving OCs containing 30 or 50 μg of ethinyl estradiol, but a slight fall, <10%, within groups of women taking these OCs.[19-21]

Few studies exist on the effect of OCs on the other

main components inhibiting coagulation—protein C and protein S. Both are vitamin K–dependent–specific plasma proteins. Protein C inactivates blood clotting factors V_a and VIII_a, and protein S serves as a cofactor for activated protein C.[22, 23] Recent reports have revealed no significant changes in the concentration of protein C in women taking OCs containing 30 μg of ethinyl estradiol[24] or unchanged or slightly increased concentrations in women taking OCs with 30 μg of ethinyl estradiol.[25-28] Conflicting results have been reported on protein S determined by different methods.[25-31] Furthermore, these studies have not considered either the type of consumption of the OC preparation or the period of blood sampling during the hormone-induced cycle. Using an assay procedure that measures total protein S, we recently reported no difference between normal women and those taking OC containing 30 μg of ethinyl estradiol, although there was a slight decrease during hormone consumption.[32]

Apparently the changes in various coagulation factors are related to the dose-dependent effect of estrogen, but the estrogen/progestogen ratio and the type of progestogen also seemed to be important.

From our ongoing study in young healthy women of the effect of two new monophasic, low-dose preparations containing new third-generation progestogens, desogestrel or gestodene, the preliminary results of the determination of the clinically relevant inhibition potential are shown in Tables I and II. There was no difference between types of treatment, that is, the treatment period is ignored by analysis on the average of each woman of the values for each sampling period or after 6 months of treatment (circumstances, Table II); antithrombin III and protein C were not significantly changed statistically, whereas total protein S decreased within the two groups, but the ranges of total protein S did not differ.

The degree of activation of the coagulation system was also assessed with plasma concentrations of thrombin–antithrombin III complexes used as a marker of thrombin formation. The concentration in plasma of thrombin–antithrombin III complexes was determined by an enzyme-linked immunosorbent assay method.[33] Regarding both treatment and the period of treatment (Tables III and IV), no significant changes were observed, and the two groups did not differ.

OCs and the fibrinolytic system

Despite an increasing knowledge of the fibrinolytic system with its various extrinsic and intrinsic pathways of activation (Fig. 2),[9, 13, 15, 34, 35] until now the clinical relevance of any deviation has mainly been associated with the extrinsic or the tissue plasminogen activator (t-PA) system, that is, the relationship between t-PA and its fast-acting plasminogen activator inhibitor type 1 (PAI-1).[13, 36]

The t-PA is produced by the endothelial cells and is secreted into the blood by mechanisms still unknown. Various stimuli and agents such as stress, exercise, catecholamines, nicotinic acid, and vasopressin analogs increased the release of t-PA from the tissue stores.[15, 35] Secretion of t-PA into the blood does not immediately result in activation of the fibrinolytic system, because in the absence of fibrin, t-PA has a very low affinity for plasminogen. However, when an intravascular clot is formed, t-PA and plasminogen bind sequentially to fibrin, resulting in the rapid generation of plasmin. This means that physiologic fibrinolysis requires fibrin not only as a substrate, as implied by the terminology, but also that fibrin acts as a stimulatory cofactor in plasminogen activation.[36, 37] PAI-1 is produced by hepatocytes, endothelial cells, and presumably megakaryocytes.[38] In the systemic circulation t-PA and PAI-1 are the major determinants of the so-called spontaneous fibrinolytic activity of blood. The introduction of new assays in recent years has made the determinations of fibrinolytic activity and the involved components not only more specific but also more reliable.

The hitherto available reports on the effects of high- and low-dose OCs on the t-PA/PAI-1 system and containing various progestogens are not that clear.

Recent studies in low-dose OCs have shown that after 3 months of treatment, t-PA activity and inhibition increased and decreased, respectively,[39, 40] as during one hormone-induced cycle[41, 42] and that the t-PA antigen level also decreased. Thus both long- and short-term administration of OCs containing 30 μg of ethinyl estradiol and 150 μg of levonorgestrel or 37 μg of ethinyl estradiol and 750 μg of lynestrenol revealed the same t-PA/PAI-1 pattern. This statement has recently been confirmed by Siegbahn and Ruusuvaara,[43] who also showed a highly age-dependent increase in t-PA antigen concentrations in normal women.

The preliminary data from our ongoing study are shown in Tables V and VI. The plasma samples were obtained from fasting persons in the morning.[44] The t-PA activity was determined in plasma euglobulin fractions by the parabolic rate assay described by Verheijen et al.[45] and expressed in international units per milliliter. The total antigen concentration in plasma of t-PA and PAI, both expressed as nanograms per milliliter, were assessed by enzyme-linked immunosorbent assay methods (Biopool Imulyse 5-t-PA and Biopool Tint-

Elize PAI-1, Biopool, Umeå, Sweden). The antibody used in the assay of PAI-1 detects equally well free PAI-1 and PAI-1 bound to activators. There were no differences between the two study groups with respect to the concentrations of t-PA and PAI-1 antigens and t-PA activity, which represent the systemic balance between t-PA and PAI-1 (Table V). However, in both groups during 6 months of treatment (Table VI), there might, despite the lack of statistical significance, be a relevant decrease in t-PA antigen level, and in particular in PAI-1 level, because t-PA activity increased significantly within both groups.

Binding of plasminogen to fibrin depends on the so-called lysine-binding sites of the plasminogen molecule. Histidine-rich glycoprotein is a plasma protein that binds to these sites, thereby decreasing the concentration of free genuine plasminogen, possibly providing a regulatory mechanism of fibrinolysis.[46]

A significant increase in plasminogen and a decrease in histidine-rich glycoprotein in plasma have been reported in studies with OCs containing <50 μg of ethinyl estradiol and containing various progestogens.[39, 47, 48] Whether this actually results in an increase in fibrinolytic capacity in women receiving OCs remains to be determined. The observed decrease in plasma histidine-rich glycoprotein was recently confirmed and found to be caused by the estrogen component.[49]

Preliminary data from our ongoing study are shown in Tables V and VI. Neither histidine-rich glycoprotein nor plasminogen differs with respect to the type of treatment, whereas within both groups, there were a significant increase in plasminogen and a decrease in histidine-rich glycoprotein, respectively, and within the same order of magnitude as previously reported.[39, 47, 48]

The fibrinolytic efficacy was estimated by a specific measurement of fibrin degradation products, and the results were expressed as micrograms per milliliter according to a calibrator delivered from the manufacturer.[50] We found no difference between treatment (Table VII), but during the treatment period, there was a slight increase within the group receiving 30 μg of ethinyl estradiol (Table VIII). No data are available in the literature for any comparison.

Concluding remarks and perspectives

The overall impression of our preliminary evaluation of two OC preparations containing third-generation progestogens is that the changes in several relevant variables within the dynamic hemostatic balance are in the same ranges, which suggests that they are independent of the ratio of estrogen/progestogen components. Moreover, the observed small changes, if any, are of the same order of magnitude as in our previously published studies[41, 42, 47, 48] and in the comprehensive study by Gevers Leuven et al.[39] This suggest an absence of a selective effect of the newer preparations, at least with respect to the hemostatic system. The lack of ratio-dependent changes might suggest a low synergistic or antagonistic effect of the progestogens.

Furthermore, the described observations seem to point to the absence of an effect on the hemostatic balance significant enough to be a possible cause of an increased risk of cardiovascular disease in normal women, as discussed extensively elsewhere.[9] In this respect the dynamic assessment of interaction between blood and the vessel wall as described by Baumgartner[51] is of particular interest and perhaps may be a relevant test to be included in future evaluations. In this model subendothelium of rabbit aorta is exposed to flowing nonanticoagulated blood in an annular flow chamber at a shear rate corresponding to the human venous system and middle-size arteries. Increased deposition

of fibrin and platelet thrombi was observed in women using OCs containing 50 μg of ethinyl estradiol[51] compared with healthy control subjects, whereas no difference was observed in women using OCs containing 20 μg of ethinyl estradiol.[52]

To verify or reject a possible link between the biochemical and epidemiologic findings, further experimental studies on the mechanisms of the effects of OCs on the hemostatic balance prospective clinical studies are needed. Furthermore, it is also extremely important to try to establish an integrated concept with respect to the hemostatic system and the carbohydrate and lipid systems. Without such an interrelated interpretation of obtained data, any evaluation might be difficult.

Studies on the mechanism of action of oral contraceptives with regard to fibrinolytic variables

Teake Kooistra, PhD,[a] Piter J. Bosma, MSc,[a] Jørgen Jespersen, MD, PhD,[b] and Cornelis Kluft, PhD[a, b]

Leiden, The Netherlands, and Esbjerg, Denmark

Evidence is provided that the fibrinolytic capacity in plasma is strongly dependent on circulating concentrations of tissue plasminogen activator rather than on concentrations of plasminogen activator inhibitor. Thus a decrease in plasma tissue plasminogen activator concentrations, as is the case in oral contraceptive users, may result in a decrease in plasma fibrinolytic capacity despite a parallel decrease in plasminogen activator inhibitor levels. It is now clear that the presence of specific intracellular receptors and a given motif in the genome are essential to mediate hormone-dependent regulation of gene expression. A computer search revealed potential estrogen and glucocorticoid-progesterone–responsive elements in the genes coding for tissue plasminogen activator, plasminogen activator inhibitor, and some other fibrinolytic variables. No convincing evidence for the presence of sex steroid receptors in endothelial cells was found, but liver cells clearly contain estrogen and androgen receptors. However, neither endothelial cells nor hepatocytes cultured in vitro showed a change in tissue plasminogen activator or plasminogen activator inhibitor synthesis on incubation with sex steroids (10^{-9} to 10^{-6} mol/L) for 3 days. An alternative explanation for the observed decreases in tissue plasminogen activator and plasminogen activator inhibitor concentrations in the plasma of oral contraceptive users is discussed. (Am J Obstet Gynecol 1990;163:404-12.)

Key words: Oral contraceptives, fibrinolysis, regulation, endothelial cells, hepatocytes

Some epidemiologic studies have suggested an association between an increase in the incidence of thromboembolic disease and the use of oral contraceptives,[1] especially for women over the age of 35 years and those who smoke.[2] The incidence of thromboembolic disease in oral contraceptive users has decreased strongly since the introduction of low-estrogen preparations, but some risk of vascular disease may still persist.[3]

Several investigators have studied the possible effects of oral contraceptive consumption on fibrinolysis, since the fibrinolytic system is generally believed to play a crucial role in the maintenance of blood vessel patency. The clinical importance of the fibrinolytic system is demonstrated by reports of a strong correlation between malfunctioning of the fibrinolytic system and hemostatic disorders.[4] Indeed, the use of oral contraceptives is associated with changes in the plasma levels of several proteins involved in the fibrinolytic system.[5-8] However, these studies of fibrinolysis in women using oral contraceptives point to an increase in blood fibrinolytic activity, which seems difficult to reconcile with an increased risk of cardiovascular disease.

The aim of the present article is twofold. First, evidence will be presented that the increase in fibrinolytic capacity in plasma from oral contraceptive users, as observed in in vitro tests may not reflect the in vivo situation. Reassessment of existing data according to our current view indicates diminished rather than increased fibrinolytic activity in the plasma of women using oral contraceptives. Insight into the regulation of the synthesis of relevant fibrinolytic variables and the effect of various pill components thereupon might ultimately enable us to design in a rational way, oral contraceptive compositions that will minimally affect the plasma fibrinolytic system. For that purpose, we will later discuss what has been learned in the past few years about the molecular mechanism of steroid hormone action, with particular reference to the synthesis of fibrinolytic components. Furthermore, we have used cultured human endothelial cells and human hepatocytes as an in vitro model system to study the regulation of essential fibrinolytic variables and the effect of various steroid hormones thereupon. The validity of this model system will be discussed.

Initiation and regulation of fibrinolysis in human plasma

Fibrinolytic activity in plasma is largely initiated by plasma plasminogen activators which generate the fibrin-degrading enzyme plasmin from its precursor

plasminogen. Because of the exceptionally low[9, 10] and labile[11] nature of plasma fibrinolytic activity in vitro, few investigators have directly studied fibrinolysis in plasma. Instead, most efforts have been directed toward study of purified components and euglobulin. The latter approaches have, according to Wun and Capuano,[12] "the limitation that important regulatory components are completely or partially eliminated . . ." However, in the most complex and undisturbed system with nonanticoagulant fresh whole blood, no spontaneous lysis occurs unless plasminogen activators are added.[13] The most complex system that still shows spontaneous lysis is described by Wun and Capuano[12, 14] and concerns a plasma clot lysis assay in which lack of lysis is overcome by avoiding fibrin cross-linking. Using this system, they demonstrated that in vitro spontaneous plasma fibrinolysis is strictly dependent on tissue plasminogen activator (t-PA)–related protein but not on urokinase plasminogen activator (u-PA) or factor XII/kallikrein, suggesting that t-PA is possibly the primary initiator of fibrinolysis in the plasma milieu. The previously demonstrated contributions of urokinase plasminogen activator and factor XII/kallikrein in euglobulin assay systems[15] are apparently not expressed in the plasma system.

Also, studies on the importance of inhibitors of clot lysis have been carried out in the plasma milieu.[12] In unclotted plasma there is a loss of t-PA-induced fibrinolytic activity which is correlated with the formation of a complex between t-PA and a specific inhibitor, plasminogen activator inhibitor-1 (PAI-1). The addition of free t-PA to t-PA-depleted plasma followed by immediate clotting results in a high rate of fibrinolysis. In contrast, when free t-PA is allowed to incubate in plasma for periods up to 60 minutes before clot formation, the fibrinolytic activity of t-PA is gradually lost. These results suggest that free t-PA is susceptible to complexation with PAI-1 in the absence of a clot: fibrin formation renders t-PA relatively inaccessible to inhibition even though the surrounding serum contains more inhibitor than t-PA.

There may be little physiologic significance to the reaction between t-PA and the "slow" inhibitors, α_2-antiplasmin, α_2-macroglobulin, and C1-inhibitor. The concentration of each of these inhibitors is about 1 μmol/L, but the reactivity with t-PA is low: the second-order rate constant for the reaction between t-PA and α_2-antiplasmin (the fastest of these reactions) is about 10^2 mol/L · s^{-1} [16] compared with 10^7 mol/L · s^{-1} for the reaction between t-PA and PAI-1.[17, 18]

How do these mechanisms of clot lysis relate to the regulation of t-PA-dependent fibrinolysis in the circulation? We can assume that t-PA is released into the circulation as free t-PA. The reaction between t-PA and PAI-1 is very fast, but because both components are highly diluted and circulate normally at levels of 0.01 to 0.3 and 0.06 to 3 nmol/L, respectively, the reaction takes 10 minutes to 1 hour to reach a high degree of completion.[4, 12] On the other hand, both t-PA and PAI-1 are rapidly cleared from the circulation; for example, for t-PA a circulatory half-life of about 4 to 10 minutes in humans has been reported[19-21] and for PAI-1, a half-life of about 10 minutes.[21] The continuous release and the relatively short retention times of t-PA and PAI-1 in the circulation compared with the time needed to complete the reaction between t-PA and PAI-1 does allow that in the circulation free t-PA and PAI-1 activity can coexist.

Thus in summary, the following model for the initiation and regulation of t-PA dependent fibrinolysis in the circulation can be imagined. In the absence of fibrin, released tissue plasminogen activator molecules are partially complexed to PAI-1 before clearance from the circulation. In the event of fibrin formation, free t-PA is adsorbed onto fibrin, which renders t-PA relatively inaccessible to inhibition by PAI-1 and other putative t-PA inhibitors in the plasma. The fibrin-bound t-PA activates the fibrin-bound plasminogen to plasmin, which degrades the fibrin. It is, among others, by this mechanism that fibrinolysis is highly fibrin localized and efficiently regulated at the plasminogen activator level.

Supportive evidence for this model has come from recent studies by Colucci et al.[22] These investigators studied the influence of endotoxin-induced elevated plasma levels of PAI-1 on thrombolysis in rabbits with a jugular vein thrombus. Infusion of t-PA resulted in a dose-dependent degree of thrombolysis that was similar in both control and endotoxin-treated rabbits, although virtually no t-PA activity was detected in the plasma euglobulin fraction of endotoxin-treated animals. These data show that the thrombolytic activity of t-PA is not affected by the presence of high concentrations of circulating PAI-1.

Effects of oral contraceptives on fibrinolysis: A reassessment

Several studies have suggested an increase in t-PA activity (usually determined in euglobulin fractions of plasma) in women receiving oral contraceptives.[5-8] This was interpreted as favoring the clot-dissolving capacity of the hemostatic system. The increase in t-PA activity was apparently not caused by an increase in t-PA antigen, which, to the contrary, was significantly reduced. The explanation was assumed to be a concomitant reduction in the amount of PAI-1. A similar situation has been observed with the anabolic steroid stanozolol[23] and with respect to the afternoon increase in t-PA activity in the diurnal rhythm.[24]

However, as outlined above, measurement of t-PA

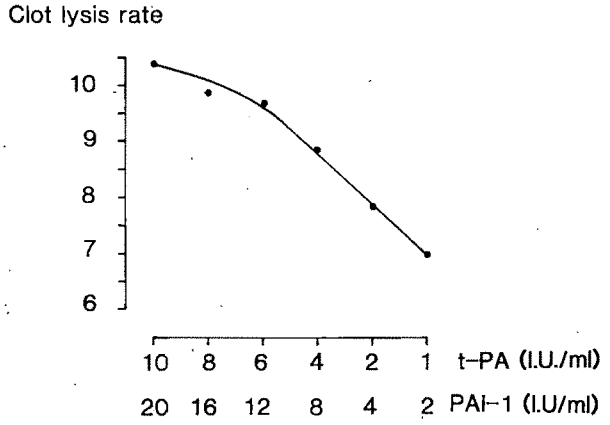

Fig. 1. Effect of decreasing amounts of PAI-1 and t-PA on plasma clot lysis rate. α_2-Antiplasmin–deficient plasma was depleted of t-PA and PAI-1 activity by prolonged incubation at 37° C. Decreasing amounts of two-chain t-PA and PAI-1 activity (from endothelial cell–conditioned medium) were added to plasma, immediately before clot formation by thrombin (final concentration, 3 NIH units/ml) and 10 mmol/L $CaCl_2$. The ratio of added PAI-1 activity to t-PA activity was 2:1 in all cases. Clot lysis rate is expressed as 1000/lysis time (in minutes). t-PA and PAI-1 activity were measured by the method of Verheijen et al.[77]

activity in plasma euglobulin fractions may not reflect the fibrinolytic capacity of t-PA in the circulation. In fact, evidence was provided that plasma fibrinolytic activity is strongly dependent on the amount of circulating t-PA rather than on PAI-1 levels. This implies that a decrease in plasma t-PA levels, as is the case in oral contraceptive users, might result in a decrease in plasma fibrinolytic activity despite a parallel decrease in PAI-1 activity. In an attempt to mimic the in vivo situation seen with oral contraceptive users, we performed a plasma clot lysis experiment in vitro, in which decreasing amounts of PAI-1 and t-PA (in a constant ratio of PAI-1 to t-PA of 2:1) were readded to plasma void of PAI-1 and t-PA activity. As shown in Fig. 1, a decrease in added t-PA resulted in a decrease in clot lysis rate despite a proportional decrease in added PAI-1 activity. This suggests that plasma fibrinolytic activity in oral contraceptive users could be diminished. It also explains why clinical studies with anabolic steroids, such as stanozolol, have not been successful in enhancing plasma fibrinolytic activity. According to these results, in the future design of an improved oral contraceptive, attention should, in our opinion, also be paid to minimizing a decrease in plasma t-PA levels.

Another reason for identifying estrogen and progestogen combinations that produce the smallest hemostatic changes is put forward by Gevers Leuven et al.[7] In a recent study on the effects of two "sub-50" oral contraceptives on plasma levels of coagulation and fibrinolysis factors, no correlations were observed between the individual changes in fibrinolytic and coagulation parameters. Thus although in both oral contraceptive–taking groups as a whole "procoagulatory" changes were stated to be balanced by "profibrinolytic" changes, in several individual cases no such compensation was seen. Therefore the use of oral contraceptives may produce individual profiles that are shifted in the direction of an increased risk of thrombosis or bleeding complications.[25] Epidemiologic data indicate that either of these disturbances occurs more frequently in oral contraceptive users than in control subjects.[26]

Molecular mechanism of steroid hormone action: The role of steroid hormone receptors and hormone response elements in the genome

Steroid hormones regulate the expression of specific genes by altering the efficiency of transcriptional initiation from their promoters. According to the "classical pathway of steroid action,"[27, 28] steroid hormone regulation of gene transcription is mediated by specific intracellular receptors in target cells, to which the hormones bind with high selectivity and affinity. On activation by hormone binding, these receptors can interact specifically with binding sites in the responsive genome, resulting in an increase or decrease in the transcription of this gene. Molecular cloning of various receptor copy deoxyribonucleic acids (cDNAs) revealed that steroid receptors are a family of hormone-dependent transcription factors having a common structural organization.[29-31] Within the steroid hormone receptor family the glucocorticoid, progesterone, mineralocorticoid, and androgen receptors are more closely related to each other in structure and function than to the estrogen receptor. The receptor protein can be divided according to sequence conservation and function into domains: an N-terminal region required for activation or repression of transcription of a gene, a central DNA-binding domain, and a C-terminal hormone-binding domain. Binding of the hormone to the receptor somehow "unmasks" the DNA-binding domain, thereby permitting specific binding to the DNA. The sites in DNA that interact with the receptor, called *h*ormone *r*esponse *e*lements (HREs), have been identified at variable distances from the promoters of a variety of steroid-regulated genes. Alignment of nucleic acid sequences in regions corresponding to identified HREs led to the definition of so-called consensus sequences (Table I). The consensus sequence for glucocorticoid response elements (GRE) and estrogen response elements (ERE) are given in Table I. No clear consensus sequence has yet been defined for progesterone, androgen, and mineralocorticoid response elements, but a GRE-15 mer is able to mediate induction by progesterone, androgens, and mineralocorticoids.[70, 71] Steroid hormone receptors

Table I. Gene regulation by steroid hormones. Consensus-responsive elements for nuclear receptors

A consensus sequence is derived from nucleotides conserved with a frequency of 50% or more.[30] A comparison of the available sequence information yields a 15-mer consensus sequence for the GRE and ERE.[28, 29, 32, 69, 70]

GRE, Glucocorticoid response element; *ERE,* estrogen response element.

*The n stands for A, T, G, or C.

probably bind to the HRE as a dimer. For example, the DNA contact sites of estrogen receptors display a perfect twofold rotational symmetry that is consistent with the dyad symmetry of the ERE sequence.[28] Similarly, recent results obtained by the same group of investigators indicate that glucocorticoid receptors bind to GREs as dimers.[32] It has been suggested that the hormone receptors bind to the HREs as head-to-head dimers and that binding involves a cooperative mechanism.

What can we learn from our understanding of the mechanism of steroid hormone action? From the previous discussion it is clear that the presence of specific intracellular receptors and a given motif in the gene is essential to mediate hormone-dependent regulation of gene expression. Thus we should at least make an inventory of the relevant genes of the fibrinolytic system and the cell types involved in their expression (the endothelial cells and hepatocytes as will be discussed) for the presence of HREs on the genes and steroid hormone receptors in the cells, respectively. It should be borne in mind, however, that the entire picture relating to steroid hormone regulation of gene expression cannot be explained by even the most explicit definition of receptors and primary DNA structure only. There are at least the following three complications: (1) All genes that are ever to be expressed in a given cell must be contained within an unraveled or accessible region of chromatin. (2) The same receptors do not regulate all similar sequences of expressed proteins in different cells or even in the same cell. This specificity is not yet understood. For example, MCF-7, a stable cell line of human metastatic breast cancer origin, secretes both t-PA and u-PA and both the t-PA and u-PA gene contain a sequence in their promoter region that matches the consensus ERE. On incubation with 17β-estradiol, however, increased synthesis of t-PA but not of u-PA was observed, whereas this increase in t-PA synthesis indeed appeared to be mediated by an estrogen receptor process and to require sustained ribonucleic acid (RNA) and protein synthesis.[33] (3) Hormone-induced intermediates can play a role and should be suspected when the lag period observed before the gene product rises is abnormally long. For instance, Rousseau et al.[34] found that in rat hepatoma cells, stimulation of the plasma membrane enzyme, alkaline phosphodiesterase I, by glucocorticoids requires RNA and protein synthesis but becomes detectable long after induction of tyrosine aminotransferase, a transcriptional effect, has taken place.

Identification of potential HREs in human fibrinolysis genes

We have examined the 5′-flanking DNA of the t-PA, u-PA, PAI-1, PAI-2, and α_2-antiplasmin genes for sequences similar to the consensus response elements for steroid hormone receptors. A computer search for the estrogen response element revealed sequences differing only in one or two nucleotides from the consensus sequence in all five genes (Table II). In the case of the u-PA gene, even two nearly perfectly conserved consensus sequences were found. A search for the glucocorticoid response element/progesterone response element disclosed the presence of only the most conserved hexanucleotide of the glucocorticoid response element/progesterone response element, TGTT/CCT, or its reverse complement, AGA/GACA, where A is adenine, C is cytosine, G is guanine, and T is thymine. These hexanucleotides were found repeatedly in the five genes (Table II). However, a palindromic sequence characteristic of many glucocorticoid/progesterone-responsive genes and possibly required in view of the discussed dimer-binding mechanism was not present. Whether such hexanucleotides in any of the five genes exert functions related to those of an authentic glucocorticoid response element/progesterone response element remains to be established.

Steroid hormone receptors in endothelial cells

Little is known about the presence of steroid hormone receptors in endothelial cells. Horwitz and Horwitz[35] have reported that aortas of dogs contain specific, high-affinity, low-capacity receptors for estrogens, androgens, and glucocorticoids. In addition, pro-

gesterone receptors could be induced by estradiol treatment. However, the receptors for the various steroid hormones are probably not in the intima because they persist when this layer is removed. Furthermore, since receptor levels were markedly lower in veins, their most likely location is in the smooth muscle of the medial layer of the artery. McGill and Sheridan[36] have investigated the presence of steroid hormone receptors in arteries from adult baboons. Of 80 sections from arteries in which endothelium could be identified, 43 (54%) had some labeled endothelial cells after injection of ^{3}H-5-α-dihydrotestosterone. Of 89 similar sections from ^{3}H-17β-estradiol–treated animals, 14 (16%) had labeling of endothelial cells. When present, endothelial cell labeling with either hormone was patchy and involved only a few contiguous cells. There was no sex difference in labeling with either hormone and in frequency of labeling among the different arteries.

Low levels of estrogen-binding sites have been found in the cytosol extracted from an endothelial cell line, which is derived from rabbit aorta endothelial cells and a rabbit fibroblast cell line.[37] Nichols et al.[38] reported the existence of classical glucocorticoid receptors in confluent bovine aorta endothelial cells but were unable to find any specific binding of [^{3}H]R1881, a potent synthetic androgen.

Steroid hormone receptors in liver cells

Estrogen. Mammalian livers of both sexes respond to sex steroid hormones. Although the human liver is not considered a classic estrogen-dependent tissue, as are the breast and uterus, it is an estrogen-responsive organ. Estrogen administration is known to alter several hepatic functions in humans (both men and women), ranging from increased secretion of many serum transport proteins to alterations in drug metabolism.[39] High-affinity, low-capacity, estrogen-specific binding proteins have been identified in the livers of several mammals including man, which suggests that the hormone may exert a direct effect on the tissue.[39-41]

Tam et al.[42] have looked for estrogen receptors in the hepatocarcinoma cell line, Hep G2. When Hep G2 cells are cultured in medium that is not supplemented with estrogen, they contain very low levels of estrogen-specific binding sites in both nuclear and cytosolic fractions. When the cells are exposed to hormone, the levels of nuclear sites increase markedly. Two nuclear-binding components can be distinguished: a high-affinity component, with a dissociation constant (K_d) for 17β-estradiol comparable with that of mammalian type I estrogen receptor and a lower affinity component, whose dissociation constant is similar to that of the type

II binding sites reported to be present in rat uterine nuclei.[43] Testosterone induces a cytoplasmic moderate-affinity, estrogen-binding component in Hep G2 cells.[44] This component may function as an estrogen "sink," which results in an increase in estrogen concentrations required for maximal induction of, for example, different apolipoproteins in Hep G2 cells.

Androgen. Male livers are strikingly androgen responsive. At first, many investigators failed to demonstrate the presence of intracellular androgen receptors, but subsequently using improved assay procedures, they were unequivocally identified.[45] Maintenance of the androgen receptor apparently requires the presence of relatively high serum concentrations of androgen, since castration of the male (rats) results in a time-dependent loss of both cytosol and nuclear receptors.[46] In accordance with this mechanism, androgen-binding activity is low in livers from females, but can be induced by testosterone treatment. As argued by Mooradian et al.,[47] many effects of androgens on liver are probably mediated by receptor-dependent mechanisms, but others are elicited directly by androgens, with the cooperation of hormones from the anterior pituitary, especially somatotropin and somatostatin.

Recently Tam et al.[44] provided evidence of the presence of high-affinity androgen receptors in the human hepatoma cell line Hep G2.

Progesterone. Several investigators have searched for progesterone receptors in liver. For example, Conneely et al.[48] used a chicken progesterone receptor cDNA probe for Northern blot analysis of total cellular RNA obtained from the livers of estrogen-treated chicks, but no detectable progesterone receptor messenger RNA (mRNA) was found. Expression of the receptor gene appeared to be highly specific for the oviduct.

Glucocorticoids. In contrast to sex hormones, which are limited in their ranges of target tissues, there are probably only a few cell types that do not respond in one way or another to glucocorticoids.[49, 50] Hepatic cells are among the major targets for glucocorticoids.[49, 51] As far as we know today, all direct effects of glucocorticoids on cells are mediated through the glucocorticoid receptor.[49, 50]

Cultured human endothelial cells and human hepatocytes as an in vitro model system to study regulation of t-PA and PAI-1 synthesis

We have examined the possibility of using cultured human endothelial cells and the human hepatoma cell line Hep G2 as an in vitro model to investigate molecular mechanisms underlying the cellular responses to steroid hormones. The t-PA in the blood stream is presumed to be derived from the vascular wall, where it is localized in the endothelial cells.[52] Although the cellular origin of plasma PAI-1 is still unknown and a contribution of other body cells cannot be excluded, we have used endothelial cells and hepatocytes as a model system to study regulation of PAI-1 synthesis. The validity of this model can be illustrated by the effects of endotoxin, cytokines, and insulin on the synthesis of PAI-1. PAI-1 in plasma behaves as an acute-phase reactant: a rapid increase in PAI-1 activity is seen after major surgery, severe trauma, and myocardial infarction.[53] In addition, PAI-1 activity can be induced in rats by intravenous injection of endotoxin or the acute phase mediators, interleukin-1, and tumor necrosis factor.[54, 55] Another example of altered PAI-1 levels in plasma has come from a study by Juhan-Vague et al.[56]: they showed a close correlation between plasma insulin levels and plasma PAI-1 levels. Both in vivo effects can be mimicked in our in vitro system. The addition of endotoxin, interleukin-1, or tumor necrosis factor to the culture medium stimulated the production of PAI-1 by endothelial cells from umbilical vein and foreskin microvessels several fold.[54, 55] On the other hand, insulin increased fairly specifically PAI-1 synthesis in Hep G2[57] and in primary cultures of human hepatocytes.[58]

Compared with the standard incubation protocol, the testing of steroid hormones in our model required some extra precautions: (1) Phenol red, which is used ubiquitously as a pH indicator in tissue culture media, bears a structural resemblance to some nonsteroidal estrogens and has significant estrogenic activity at the concentrations (15 to 45 μmol/L), at which it is found in tissue culture media.[59] Phenol red binds to the estrogen receptor of MCF-7 human breast cancer cells with an affinity 0.001% that of estradiol ($K_d = 2 \times 10^{-5}$ mol/L). Cells used in our studies were therefore cultured and maintained in culture media void of indicator. (2) Maintenance of Hep G2 cells in a wide range of estradiol concentrations indicated that adjustment of the medium to 20 nmol/L in hormone every 12 hours was adequate to maintain nuclear binding at 90% of the maximal levels obtainable.[42] This is considerably higher (about 20-fold) than peak circulating concentrations of estradiol found in premenopausal nonpregnant women, but since hepatocytes metabolize the hormone extremely rapidly ($t_{1/2}$ = 1 hour), the effective steady-state concentrations of the hormone in the culture system are likely to be considerably lower. Consequently, it is not possible to equate the nominal concentrations in the cultures with circulating in vivo levels. (3) When Hep G2 cells are cultured in medium that is not supplemented with estrogen, they contain very low levels of estrogen-specific binding sites in both nuclear

Table III. Effect of steroid hormones on the production of t-PA and PAI-1 by cultured human endothelial cells and Hep G2 cells

	Endothelial cell CM		*Hep G2 CM*
Hormone added	*t-PA*	*PAI-1*	*PAI-1*

Gestodene	95% ± 2%	105% ± 1%	103% ± 4%

CM, Conditioned media.

Endothelial cells from human umbilical veins (only female vessels were used) were isolated and cultured as previously described.[55] Conditioned media were obtained by incubating second-passage, confluent cells at 37° C for 3 consecutive periods of 24 hours in M199-medium (indicator-free), supplemented with 10% (v/v) human serum, 20 mmol/L HEPES, glutamine, penicillin, streptomycin, 0.01% (v/v) ethanol, and with or without hormone (10^{-9}, 10^{-8}, or 10^{-7} mol/L). Every 24 hours, conditioned media were collected and fresh medium was added to the cells. Conditioned media were immediately centrifuged (to remove cellular debris) and stored at −20° C.

The cell line Hep G2 was subcultured and grown as previously described.[58] To obtain conditioned media, cells were grown to about 50% confluency and incubated at 37° C in minimum essential medium Eagle with Earle's salts (EMEM) (indicator-free), which was supplemented with 10% (v/v) fetal bovine serum, glutamine, penicillin, streptomycin, 0.01% (v/v) ethanol, and with or without hormone (10^{-8}, 10^{-7}, or 10^{-6} mol/L), exactly according to the protocol described above for endothelial cells. Each experiment was performed with incubations in duplicate. The t-PA antigen levels were assayed by enzyme immunoassay (Biopool, Umeå, Sweden). PAI-1 activity was measured by the method of Verheijen et al.[77] Values were expressed as percentage values relative to control values. The data shown represent means ± range of two separate experiments, after 72 hours of incubation in the presence of 10^{-7} mol/L (endothelial cells), or 10^{-6} mol/L (Hep G2) hormone.

and cytosolic fractions. A high-affinity binding component increased relatively rapidly to reach approximately 50% and 80% of the 48-hour level within 3 and 8 hours, respectively, after initial exposure to 20 nmol/L of the hormone.[60] In contrast, induction of a low-affinity component had a lag of several hours and only reached 10% of the 48-hour level 8 hours after the addition of hormone. Thereafter it accumulated rapidly to 90% of the 48-hour level within 24 hours. The increase in the level of high-affinity nuclear estrogen binding sites was accompanied by an increase in the levels of apolipoprotein-A_1 mRNA and secreted protein. New steady-state levels of apolipoprotein-A_1 mRNA and the rate of apolipoprotein-A_1 protein synthesis, approximately twice those of control cultures, were established within 24 to 48 hours of exposure to 17β-estradiol. These increases in apolipoprotein-A_1 levels were obtained when estradiol was added either to dividing cells or to cultures that had just reached confluency.[42] However, a decreased response was observed in cells that had been confluent for periods beyond 24 hours before hormone treatment. In our protocol, Hep G2 cells were grown to 50% confluency before hormone was added to the medium. The incubation medium was refreshed every 24 hours for 3 days. Usually cells reached confluency after 2 days. (4) Seillan et al.[61] studied the effect of testosterone (10^{-8} mol/L) and 17β-estradiol (10^{-8} mol/L) on the secretion of prostaglandins (I_2, E_2, and $F_{2\alpha}$) by cultured endothelial cells from male and female piglets. After 5 days of incubation, cells from female aortas responded to testosterone and 17β-estradiol by a marked increase in prostaglandin secretion (three to five times), whereas endothelial cells from male animals were insensitive to androgen and estrogen. In addition, in male cells no steroid degradation was observed, whereas in female cells, both testosterone and estradiol were partially metabolized. Therefore in our experiments we used only endothelial cells from female umbilical veins. In this respect, it should be noted that the Hep G2 cell line was established from a liver tumor biopsy of a boy.[62]

Effect of steroid hormones on the production of t-PA and PAI-1 in cultured endothelial cells and hepatocytes

We have cultured endothelial cells and Hep G2 cells for periods up to 72 hours in the presence of maximally 10^{-7} and 10^{-6} mol/L steroid hormone, respectively. Under these conditions, 17β-estradiol has been reported to stimulate endothelial cells to increase their production of von Willebrand factor about 1.7 times, albeit that estradiol also caused a slight increase in cell replication.[63] Similarly, 17β-estradiol increased apolipoprotein A_1 synthesis in Hep G2 about twofold.[42, 44, 60] However, as shown in Table III, none of the hormones tested, that is, estradiol, ethinyl estradiol, testosterone, methyltestosterone, progesterone, levonorgestrel, and gestodene, showed a significant effect on the production of t-PA or PAI-1 in either cell type. Comparable results were obtained at shorter incubation periods (24

or 48 hours), at lower hormone concentrations, or when PAI-1 antigen (Biopool Imulyse PAI-1 assay) rather than PAI-1 activity was measured (results not shown). In several cases, hormones were tested at lower serum concentrations (1%), or subconfluent cultures of endothelial cells were used but without effect. Maintaining endothelial cells or Hep G2 in the presence of hormone had no detectable effect on their viability compared with control cultures.

Our results indicate that cultured endothelial cells and Hep G2 cells cannot easily be used as a model system to study the effect of pill components on the synthesis of fibrinolytic variables in vitro. A similar experience was obtained in testing stanozolol in our in vitro model (unpublished results).

Several concluding remarks are to be made. Evidence is provided that the fibrinolytic capacity in plasma is dependent on circulating t-PA levels rather than on PAI-1 activity. The view that the reported decrease in plasma t-PA protein after oral contraceptive use is compensated by the concomitant decrease in PAI-1 level is questioned. It is argued on both theoretic and experimental grounds that a decrease in plasma t-PA levels as observed in oral contraceptive users is associated with a decrease in plasma fibrinolytic capacity. For future design of an improved oral contraceptive, maintenance of normal plasma t-PA levels should be pursued if possible.

In the second part of this article, studies on the mechanism of action of oral contraceptives at the cellular level are reviewed. It is now clear that the presence of a given motif in a gene and the presence of a specific intracellular receptor can mediate hormone-dependent regulation of gene expression. A computer search revealed potential estrogen response elements in the t-PA, u-PA, PAI-1, PAI-2, and α_2-antiplasmin genes. Because we assumed that endothelial cells and hepatocytes are the main sources of plasma fibrinolytic components, we have searched the literature for the presence of steroid hormone receptors in these cells. In contrast to glucocorticoid receptors, no convincing evidence for the presence of sex steroid receptors in endothelial cells was found. In addition to glucocorticoid receptors, liver cells clearly contain estrogen receptors (in both male and female cells) and androgen receptors (normally in male cells, but inducible in female cells), whereas no progesterone receptors in these cells could be detected. These data suggest the possibility that PAI-1 synthesis in hepatocytes (these cells do not produce t-PA) is regulated by estradiol by way of a receptor-mediate pathway and an estrogen response element in the PAI-1 gene. However, this possibility is not supported by our in vitro experiments: Hep G2 cells did not respond to estradiol or ethinyl estradiol with respect to PAI-1 synthesis. In fact, neither endothelial cells nor Hep G2 cells showed a change in t-PA or PAI-1 synthesis on addition of any of the hormones tested. Therefore our in vitro model system provides no evidence for diminished synthesis of t-PA and PAI-1 as a direct effect of the hormones.

The plasma level of a molecule is the result of two processes, influx and clearance. Thus an alternative way in which oral contraceptive components could reduce plasma levels of t-PA and PAI-1 would be an increase in the clearance rate of both proteins, for example, by an increase in the number of receptors. Indeed, several studies report that the number of cell surface receptors for a ligand can be under hormonal control. Poola and Lucas[64] found that the oviduct has an estrogen-inducible transferrin receptor. Estrogen has also been shown to enhance the number of low-density lipoprotein receptors present on rabbit hepatocytes[65] and Hep G2 cells[66] and to enhance epidermal growth factor receptors in rat uterine.[67] Treatment of postmenopausal women with low doses of 17β-estradiol and *dl*-norgestrel significantly lowered very low–density lipoprotein triglycerides in four of five subjects by enhancing their clearance.[68] It is likely that as a greater number of systems are studied, estrogen and perhaps other steroid hormones, will be found to play a significant role in regulating a number of cell surface receptors. Whether these receptors will include receptors for t-PA or PAI-1 remains to be established.

Metabolic changes during the normal menstrual cycle: A longitudinal study

Anne-Mette Lebech, MD, Andreas Kjær, MD, and Paul E. Lebech, MD
Copenhagen, Denmark

The effect of sex hormones on lipid metabolism and coagulation during the menstrual cycle was studied in 37 women. Each woman had three samples drawn, corresponding to the follicular phase, midcycle, and the luteal phase. Basal conditions were obtained by taking samples in the morning while subjects were still in bed. No changes were found in lipids and lipoproteins during the menstrual cycle. Antithrombin III and factor VII of the coagulation system did not change throughout the cycle. Fibrinogen increased in the luteal phase, and all samples of fibrinogen correlated positively with progesterone concentration. This increase, therefore, could be a progesterogenic effect. In conclusion, these findings suggest that when studied optimally no changes in lipids and lipoproteins are found and that the day of blood samples is of minor importance, for instance, when used as a control in studies of oral contraceptives. For investigations on some coagulation parameters, the days of the cycle may be of importance. (Am J Obstet Gynecol 1990;163:414-6.)

Key words: Menstrual cycle, lipid metabolism, blood coagulation

Sex hormones influence lipid metabolism and produce changes in the coagulation system. Several studies have been undertaken in women taking oral contraceptives, but in addition, it would be of interest to investigate if the changes in sex hormones seen during the normal menstrual cycle could induce changes in lipids and coagulation.

In this study we investigated possible changes in some coagulation parameters and lipids and lipoproteins, including the high-density lipoprotein 2 (HDL_2) fraction and apolipoproteins.

Material and methods

Thirty-seven apparently healthy, nonobese women took part in this study. Their median age was 25 years (range, 19 to 36 years). All had regular menstrual cycles (25 to 36 days).

Blood samples were drawn three times during the cycle: days 6 to 8 (follicular phase), days 12 to 14 (midcycle), and days 24 to 26 (luteal phase). Samples were taken in the morning while subjects were still in bed at home. Blood samples were spun and serum or plasma withdrawn.

The following hormones were measured by radioimmunoassay: 17β-estradiol, progesterone, luteinizing hormone, follicle-stimulating hormone, and prolactin.

Triglyceride and total cholesterol levels were determined by enzymatic methods with commercial kits (Boehring, Federal Republic of Germany). High-density lipoprotein cholesterol was determined in the supernate after precipitation of apolipoprotein B–containing lipoprotein with phoshotungstate/magnesium^{2+}.[1] Low-density lipoprotein cholesterol was determined indirectly by means of the Friedewald formula.[2] Determination of HDL_2 was done by a modification of a two-step precipitation method.[3] Apolipoproteins were measured by electroimmunoassay in agarose gel.

Antithrombin III was assessed functionally,[4] factor VII by a commercial kit (Dade AG, CH), and fibrinogen by coagulimetry as the difference in diffused light.

Statistical evaluation was performed with analysis of variance followed by Duncan's test. Correlation was expressed by Pearson's r, and $p < 0.05$ was chosen as level of significance.

Results

Table I presents the serum levels of hormones. 17β-Estradiol was three to four times higher at midcycle (days 12 to 14) and two to three times higher in the luteal phase (days 24 to 26) than in the follicular phase (days 6 to 8). Progesterone was 10 to 15 times higher in the luteal phase than in the follicular phase or at midcycle. Follicle-stimulating hormone decreased in the luteal phase, and luteinizing hormone showed a maximum at midcycle. Prolactin did not change through the cycle.

Results of the lipid parameters are shown in Table II. None of the serum lipids, lipoproteins, or apolipoproteins changed throughout the cycle.

†$p < 0.05$, ††$p < 0.01$, and †††$p < 0.001$ vs days 10 to 12.

Table II. Lipid concentrations and apolipoprotein levels during the menstrual cycle (mean ± SEM)

	Cycle days		
	6-8, follicular phase	*10-12, midcycle*	*24-26, luteal phase*
Triglycerides (mmol/L)	0.89 ± 0.06	0.93 ± 0.07	0.93 ± 0.07
Total cholesterol (mmol/L)	4.61 ± 0.15	4.58 ± 0.17	4.34 ± 0.16
LDL cholesterol (mmol/L)	2.81 ± 0.14	2.78 ± 0.15	2.58 ± 0.13
HDL cholesterol (mmol/L)	1.71 ± 0.08	1.70 ± 0.08	1.61 ± 0.07
HDL_2 cholesterol (mmol/L)	0.48 ± 0.06	0.52 ± 0.05	0.42 ± 0.06
Apolipoprotein A_1 (gm/L)	1.20 ± 0.03	1.18 ± 0.03	1.19 ± 0.03
Apolipoprotein B (gm/L)	0.87 ± 0.04	0.87 ± 0.04	0.84 ± 0.04

LDL, Low-density lipoprotein; *HDL,* high-density lipoprotein.

Table III. Plasma concentration of antithrombin III, factor VII, and fibrinogen in the menstrual cycle (mean ± SEM)

	Cycle days		
	6-8, follicular phase	*10-12, midcycle*	*24-26, luteal phase*
Antithrombin III (%)	106.4 ± 2.3	106.3 ± 1.7	107.5 ± 1.8
Factor VII (%)	117.2 ± 7.8	104.3 ± 5.4	98.1 ± 5.0
Fibrinogen (nmol/L)	7.30 ± 0.29	7.29 ± 0.23	8.18 ± 0.28*†

*$p < 0.05$ vs days 6 to 8.
†$p < 0.05$ vs days 10 to 12.

Table III shows antithrombin III, factor VII, and fibrinogen values. Only fibrinogen showed a change. A 12% increase was found in the luteal phase when compared with the follicular phase and midcycle. Fibrinogen concentrations correlated positively with progesterone concentrations ($n = 108$; $r = 0.28$; $p < 0.01$).

Comment

Hormone values show results confirming that the samples were drawn in the follicular phase, at midcycle, and in the luteal phase. Total cholesterol and triglyceride values did not change in our study, which is in agreement with Demacker et al.[5] However, according to Kim and Kalkhoff[6] and Adlercreutz and Tallqvist,[7] changes were found. These differences could be explained on the basis of the larger number of women and the longitudinal design of our study.

High-density lipoprotein and low-density lipoprotein cholesterol did not fluctuate throughout the cycle, which is inconsistent with Hemer et al.[8] and Demacker et al.[5] Other authors have found changes in high-density lipoprotein and low-density lipoprotein cholesterol throughout the cycle.[9] This discrepancy could apart from the larger group and longitudinal design of our study be explained by the optimized blood collection procedure that consisted of drawing the samples early in the morning and before subjects got out of bed; confirmation of basal conditions is the high prolactin levels resulting from sleep-associated augmentation.[10] HDL_2 cholesterol has, as far as we know, not been previously measured in the normal menstrual cycle. This interesting subfraction in respect to cardiovascular disease did not change nor did apolipoprotein A_1, which is its main carrier protein. The changes in sex hormones are probably of too short duration to affect the liver's metabolism of lipoproteins, and this

could explain the absence of changes found in lipids.

However, fibrinogen, which is also produced in the liver, rose in the luteal phase, which seems to be a progesterogenic effect according to the positive correlation found. Antithrombin III did not change throughout the cycle. Some authors, however, have found minor changes.[11]

In conclusion, we found that if a longitudinal study performed under optimal conditions on a large group of women is made, no changes in lipids and lipoproteins can be found throughout the menstrual cycle. Therefore the day of the cycle on which blood samples are drawn, for instance, as control values, in studies of lipid metabolism in women taking oral contraceptives seems to be of minor importance. When coagulation is studied, the day may be of some importance for some variables.

Influence of oral contraceptives on coagulation tests in native blood and plasma

Friedebert Kunz, MD,[a] Christoph Pechlaner, MD,[a] Marco Tabarelli, MD,[b] Elisabeth Sölder, MD,[b] and Wolf-Dieter Zwierzina, MD,[a]
Innsbruck, Austria

Routine coagulation laboratory tests, clotting times in native (not anticoagulated) whole blood, platelet-rich and platelet-poor plasma, and recalcification times in citrated whole blood, platelet-rich and platelet-poor plasma were performed in 14 healthy premenopausal women. Blood was taken before and after one or two cycles of low-dose oral contraceptives. After oral contraceptives a reduction in clotting time in native platelet-rich plasma and activated partial thromboplastin time were observed. Recalcification times in whole blood and platelet-rich plasma were shorter than clotting times in their native counterparts. The observed changes are compatible with a procoagulant effect seen soon after the start of oral contraceptive use. The absence of these changes in the recalcification times in citrate systems suggests a masking effect of citrate. The reduction in clotting times in native platelet-rich but not in platelet-poor plasma indicates that the hypercoagulability in oral contraceptives users is mainly related to platelets. (AM J OBSTET GYNECOL 1990;163:417-20.)

Key words: Oral contraceptives, coagulation, native blood, activated partial thromboplastin time

There is a vast body of literature on changes in blood coagulation in users of oral contraceptives (OCs) and the induction of a hypercoagulable state, which is defined as procoagulatory changes in some coagulation tests (accelerated clotting or changes in clotting factors or inhibitors).[1-5] Much of the published data is conflicting, which partly reflects technical differences in the assay systems, as well as problems in an accurate diagnosis of deep vein thrombosis.[6,7] The insufficient reliability of epidemiologic data reporting an association between OC use and deep vein thrombosis has been discussed extensively.[8]

There is also no consensus on the relevance of the reported hemostaseologic findings, for example, a decrease in antithrombin III or a rise in fibrinogen concentration.[9] On the other hand, divergent effects may compensate each other, as may be the case with reported procoagulatory and profibrinolytic effects.[10]

To date there is no coagulation laboratory test available for assessment of individual thromboembolic risk.

In our laboratory we developed clotting tests in native (i.e., not anticoagulated) blood and plasma, which revealed hypercoagulability in coronary heart disease and diabetes mellitus (unpublished data) not disclosed by the conventional citrate test systems. This prompted us to examine, with these test systems, the effects of low-dose OC use on blood coagulation, with test persons serving as their own control.

Material and methods

Fourteen healthy women taking no other medication (particularly no medication known to influence coagulation or platelet function for at least 14 days) participated after they gave informed consent. All used low-dose OC formulations (containing ethinyl estradiol, 0.03 mg in 13 patients and 0.04 mg in 1 patient). They were examined in the second half of the menstrual cycle before and between the eighteenth and twenty-first day of the first (nine women) or second (five women) cycle of OC use.

All clotting time measurements were performed in duplicate on a hook coagulometer (Amelung, Lemgo, West Germany) at 37° C. Blood was obtained by atraumatic puncture of an antecubital vein through a 1.2-gauge needle. In citrated samples 9 volumes of blood were mixed with 1 volume of 0.11 mol/L sodium citrate (Sarstedt tubes, Vienna, Austria).

Immediately after blood collection, 0.3 ml of native whole blood was transferred to the coagulometer, and clotting time was recorded.

The preparation of native platelet-rich and native platelet-poor plasma was carried out at 4° to 10° C by differential centrifugation (5 minutes at 400 *g* for native platelet-rich plasma; 10 minutes at 2000 *g* for native platelet-poor plasma). Cooling is essential to prevent coagulation. Contact with glass surfaces was avoided. Native platelet-rich plasma was adjusted to a platelet

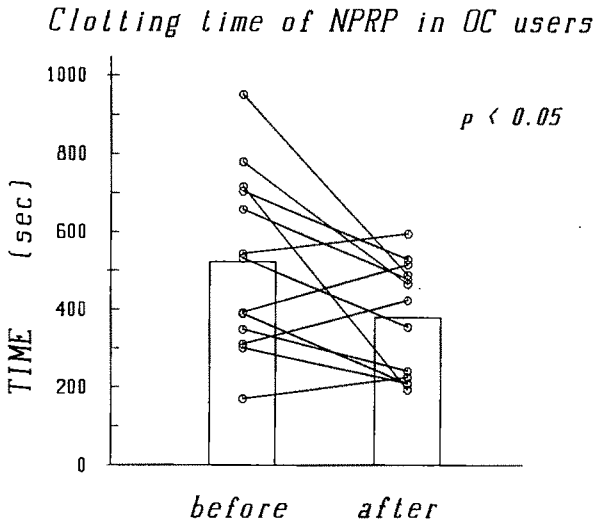

Fig. 1. Clotting times in native platelet-rich plasma *(NPRP)* before and after OC use. *Bars* denote the means of 13 values. (Data are missing in 1 of 14 cases.)

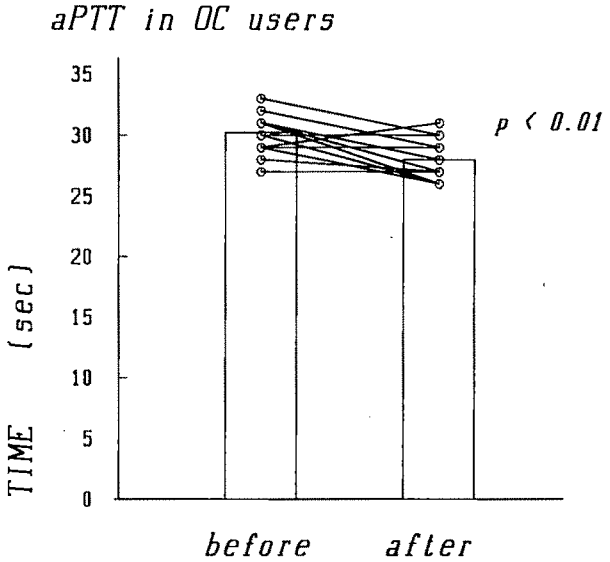

Fig. 2. Activated partial thromboplastin time *(aPTT)* (in citrated plasma) before and after OC use. *Bars* denote the means of 14 values. Some points and lines are overlapping.

concentration of 250 G/L by addition of autologous native platelet-poor plasma. Clotting times were recorded in 0.3 ml samples.

In the citrated systems, recalcification times in 0.2 ml samples were recorded after the addition of 0.2 ml of 0.025 mol/L $CaCl_2$.

A platelet count was performed on a Coulter counter in whole blood, platelet-poor plasma, and before and after adjustment of the platelet concentration in platelet-rich plasma (both in native and citrated samples).

Routine coagulation tests were performed on citrated blood or plasma, according to the instructions of the manufacturers: activated partial thromboplastin time (cephaloplastin Dade, Merz + Dade, Düdingen, Switzerland), partial thromboplastin (Boehringer, Mannheim, West Germany), fibrinogen,[11] antithrombin III (Boehringer), and thrombelastography[12] (Hellige thrombelastograph D, Freiburg, West Germany). A blood count was carried out on a Coulter counter.

The Wilcoxon matched-pairs signed-ranks test was used to test for statistically significant differences; correlations were tested according to standard nonparametric procedures. BMDP statistical package subprograms 3D and 8D, respectively, (BMDP statistical software, Inc., Los Angeles, Calif.) were applied.

Results

A significant reduction in clotting times was observed in native platelet-rich plasma (Fig. 1) and activated partial thromboplastin time (Fig. 2) after OC use but not in the other test systems (Table I). Neither the increase in fibrinogen concentration nor the decrease in antithrombin III was statistically significant (Table I).

Clotting times in native whole blood and platelet-rich plasma were significantly longer than in their citrate counterparts before OCs ($p < 0.01$; Table I); after OCs only the whole blood methods differed significantly ($p < 0.05$; Table I).

Platelet counts in native and citrated platelet-rich plasma before adjustment to 250 G/L did not differ significantly (339 ± 112 vs 348 ± 82 G/L).

Coagulation test changes did not differ between first and second cycle. No correlation was observed between changes in clotting times of native platelet-rich plasma and activated partial thromboplastin time.

Comment

There is still ongoing debate on whether OC use induces the development of hypercoagulability or increases the risk of deep venous thrombosis, especially if the newer low-dose formulations are used. The establishment of a correlation between OC use and clinically manifest thromboembolic disease is confounded by a rather high rate of false-positive and false-negative errors in clinical diagnosis. However, clinical experience suggests an influence of OC use, because in young women deep vein thrombosis appears to occur almost exclusively in OC users or in very obese persons. In an ongoing study at our clinic, 24 of 37 premenopausal women with deep vein thrombosis received OCs (prevalence of OC use in our area is 25%); of the remaining 13 women, 8 were obese.

The most commonly reported blood coagulation alterations in OC users are a decrease in antithrombin III and an increase in platelet aggregability and fibrinogen, all compatible with a shift to hypercoagula-

bility.[3-5, 8] However, not all investigations confirmed these results[15]; in our study the lack of significant differences might be because of the small number of patients. On the other hand, several papers[9, 14] report an increase in fibrinolytic activity, which may compensate for procoagulant changes.

The significant shortening of clotting time in native platelet-rich plasma but not in the other native test systems observed in our study suggests a role of platelets in mediating the effects of OCs. An increase in platelet activation has been described in other reports, however, not unanimously.[2]

The additional influence of erythrocytes[15] is probably the main reason why these changes between before and after OC use were not seen in whole blood. Another reason might be activation of platelets and/or coagulation by cooling; this, however, appears to be of minor relevance, because in uncooled citrate the clotting time of platelet-rich plasma was shorter than in cooled native platelet-rich plasma.

The lack of differences in recalcification times in the citrate systems before and after OC use points to a masking effect of citrate, probably because of a platelet-aggregating effect. This is in agreement with results of another study[15] in native blood in which a sex difference in platelet aggregation with stronger platelet aggregation responses in women, not detectable in citrate, was observed. The differences between native and citrate systems may be caused by altered platelet function as a consequence of reduction as well as Ca^{2+} availability of increased pH in citrate.[16, 17] Since the platelet concentration before adjustment to 250 G/L was the same in native and citrate platelet-rich plasma, a different platelet distribution can be ruled out as the reason for the differences between native and citrate systems.

As illustrated in Figs. 1 and 2, the decrease in clotting time was not uniformly observed in all subjects, which indicates differing individual reactions. Moreover, changes in the same persons were not unidirectional in native platelet-rich plasma and activated partial thromboplastin time, which is not surprising, since partly different phases of coagulation were tested.

The observed reduction of activated partial thromboplastin time has also been reported by some other groups,[2, 14, 18] which suggests changes in intrinsic plasma coagulation factors in OC users, for example, increased factor XII concentration.[9]

One of the several reviews[8] on the subject came to the conclusion that "at this time, it is not known whether oral contraceptives do or do not trigger the hemostasis system to develop a thrombosis or by which mechanism they could trigger the event." Our data speak in favor of an effect of OC use (including the low-dose formulations) on blood coagulation, with a shift toward faster clotting demonstrable after one to two pill cycles. This seems to be mediated at least in part by increased reactivity of blood platelets, which is detectable in native but not in citrate blood.

The impact of the type of sex steroids used and other cofactors (e.g., smoking) needs further study. Whether the detected changes will still be observed after a longer period of OC use still needs to be determined.

We are indebted to Mrs. Sedighe Ahrabian for excellent technical assistance and to Dr. Arnulf Lochs for expert help on statistical and computational problems.

Hemostasis profile in women taking low-dose oral contraceptives

J. L. David, MD,[a] U. J. Gaspard, MD, PhD,[b] D. Gillain, MSc,[b] R. Raskinet,[a] and M. R. Lepot, MD[b]

Liège, Belgium

Thirty-six young, healthy, nonsmoking women have been selected to check the effect of low-dose oral contraceptives on hemostasis. Two identical groups were treated by Marvelon (a monophasic oral contraceptive containing ethinyl estradiol and desogestrel) or Trigynon (a triphasic oral contraceptive containing ethilyl estradiol and levonorgestrel) for a 6-month period. In the absence, previously controlled, of substantial differences between the effects of each treatment on hemostasis, all the results were pooled at the third and sixth month of the study. The effects of oral contraceptive treatment were as follows: (1) platelet number, platelet aggregating ratio, and plasma β-thromboglobulin level were not significantly altered, and (2) antithrombin III activity was not reduced despite a slight decrease or antigen concentration. The von Willebrand factor parameters, factor VIII:C, factor VII:C, and clottable fibrinogen were significantly increased. Plasminogen (activity and antigen concentrates) and α_2-antiplasmin levels were also significantly increased. Activated partial thromboplastin time and euglobulin lysis time measured after venous occlusion were significantly shortened. Although statistical analysis did not show dramatic changes in all these parameters, some individual extreme values were substantially altered. Therefore we believe that these later values are worthy of cautious consideration for weighing the role that hemostasis factors might play in individual thrombotic risk. (AM J OBSTET GYNECOL 1990;163:420-3.)

Key words: Oral contraception, platelets, von Willebrand factor, coagulation, fibrinolysis

Despite an overall reduction of thrombotic events in users of low-dose oral contraceptives, recent epidemiologic data are consistent with an increased risk of deep venous thrombosis and pulmonary embolism in treated women.[1] The thrombotic risk linked to oral contraceptive use is probably multifactorial, involving diverse alterations in hemostasis.[2] It is generally accepted that these later alterations are induced by the estrogen component of oral contraceptives and are dose related.[3,4] The estrogenic effect may be under a modulating influence of progestogens.

According to several recent studies, no dramatic changes in the hemostatic profile were observed in selected women treated by low-dose oral contraceptives, although some significant modifications of coagulation and fibrinolysis have been reported.[5, 6] However, we wondered whether some individual values of hemostasis variables could not have reached a level largely beyond the usually accepted reference range. Such individual alterations on hemostasis should be noticed, taking into account that epidemiologic studies have shown a positive correlation between the thrombotic risk and the level of fibrinogen and factor VII:C.[2]

Therefore in this study, we have considered not only the statistical dispersion but also the extreme values of parameters such as platelets, von Willebrand factor, coagulation, and fibrinolysis tested in a homogeneous cohort of 36 young healthy, nonsmoking women. This cohort was divided in two groups, each of whom received for 6 months one of two widely used low dose preparations, Marvelon (mono-DG), a monophasic oral contraceptive containing ethinyl estradiol (30 mg) and desogestrel (150 mg), and Trigynon (trilevonorgestrel), a triphasic oral contraceptive containing ethinyl estradiol and levonorgestrel (6 days ethinyl estradiol, 30 mg + levonorgestrel, 50 mg; 5 days ethinyl estradiol, 40 mg + levonorgestrel, 75 mg; 10 days ethinyl estradiol, 30 mg + levonorgestrel, 125 mg).

In this article, the results of both groups have been pooled after we observed that there was no substantial difference between the effects of each preparation on hemostasis.

Material and methods

Thirty-six women between 21 and 34 years of age were nonsmoking healthy volunteers. Some had stopped oral contraceptives for at least 8 weeks before the study, and the others had never used oral contraceptives. These women were treated with Marvelon (mono-DG group) or Trigynon (tri-LNG group). The use of aspirin or of other nonsteroidal antiinflammatory drugs was avoided during the study. A hemostatic control was performed during the last untreated cycle, 7 days before presumed menstruation. The oral contraceptive treatment was continued for six cycles. Hemostatic controls were performed between days 18 and 21 of the third and sixth months of treatment. Thus each woman served as her own control.

Venous samples of blood were taken in fasting women at rest. Platelets were enumerated by a Coulter counter. Platelet aggregate ratio was computed by counting free platelets on whole blood sample, which gave an index of circulating aggregates.[7] Plasma β-thromboglobulin was measured by radioimmunoassay after suitable blood sampling.[8] The von Willebrand factor was evaluated by its related antigen (vWF:Ag) measured by electroimmunodiffusion[9] and by its ristocetin cofactor activity.[10] Activated partial thromboplastin time, clottable fibrinogen, factor VIII:C, and factor VII:C were determined according to the principles of routine techniques. Antigenic levels of antithrombin III and plasminogen were determined by radioimmunodiffusion with plates purchased from Behring. Antithrombin III, plasminogen, and α_2-antiplasmin activities were assessed on chromogenic substrates. Samples for euglobulin lysis time were taken before and at the end of venous occlusion produced for 10 minutes by application of a cuff round the upper arm, which was inflated to a level midway between systolic and diastolic blood pressure. Euglobulin lysis time was determined in samples taken before venous occlusion and immediately before the depletion of the cuff.[11]

Statistical analysis. Results collected before and at the third and sixth months of the oral contraceptive treatment period were compared by a paired *t* test with use of an SAS program.[12] Moreover, the highest (+) or the lowest (−) extreme values of the ranges were selected for each parameter considering their hypothetic involvement in the thrombogenesis.

Results

Platelets. Platelet number, platelet aggregate ratio, and plasma β-thromboglobulin levels were not significantly modified during the treatment period.

No thrombocytosis occurred in any women, but low platelet aggregate ratio (increase in circulating aggregates) and high β-thromboglobulin plasma levels released from platelets were observed as shown by the extreme values (Table I).

The von Willebrand factor. The von Willebrand factor (vWF:Ag) but not ristocetin cofactor was significantly increased in treated women. The extreme values of the von Willebrand factor remained below 200% during the treatment period; extreme values of the ristocetin cofactor were already high before treatment.

Coagulation. Oral contraceptive treatment induced a significant increase in clottable fibrinogen, factor VII:C, and factor VIII:C levels (except for the latter at the third month). The highest extreme value of clottable fibrinogen was above usual upper reference values. The highest extreme value of factor VIII:C, which was observed at the sixth month, was the most impressive result of the study. In addition, only factor VIII:C was significantly increased from the third to the sixth month.

Antithrombin III activity was not significantly modified during the whole treatment period despite a significant decrease in its antigen concentration. However, at the sixth month, the lowest extreme value of antithrombin III activity was inferior to its corresponding baseline value.

Fibrinolysis. Both plasminogen antigen concentration and activity were significantly increased by oral contraceptives, mainly at the third month. The α_2-antiplasmin activity was significantly increased at the

third month and tended to remain elevated at the sixth month ($p = 0.0556$), with a more marked dispersion of the results.

The euglobulin lysis time (Table II) was significantly shortened only after venous occlusion.

Comment

Although most of the parameters controlled in this study were significantly modified during low estrogen oral contraceptive treatment, the alterations in mean and SD values were not very marked. These results are in accordance with those reported in other comparable studies.[13, 14] However, we believe that the extreme values observed among individual results were worthy of consideration, taking into account their possible involvement in the multifactorial pathogenesis of thrombotic events.

Thus the mean values of platelet aggregate ratio and plasma β-thromboglobulin were not significantly modified by oral contraceptives, but their extreme values strongly suggest that an in vivo platelet activation occurred in some healthy women during the treatment period.

The von Willebrand factor (vWF:Ag) was significantly increased during the treatment period and ristocetin cofactor was already increased before it. Although the meaning of elevation in von Willebrand factor is not clearly documented, it must be remembered that this factor is released from platelets and endothelial cells, thus playing a crucial role in platelet adhesion when the flow rate is such as to give high-wall shear stress.

The increase in factor VII:C, factor VIII:C, and fibrinogen was probably the result of the well-known effect of estrogen on protein synthesis by hepatocytes.

High levels of these factors do not imply an in vivo activation of coagulation, although epidemiologic studies have reported that thrombotic risk was linked to the level of fibrinogen and factor VII:C.

In our study, activated partial thromboplastin time, an ex vivo dynamic test of coagulation, was significantly shortened by oral contraceptive treatment, but its shortest time remained within the normal range of the usual laboratory references.

Antithrombin III activity, the main natural inhibitor of coagulation, was not reduced despite a slight but significant lowering of its antigenic plasma concentration.

As for coagulation factors, the increase in plasminogen and α_2-antiplasmin was probably induced by a nonspecific effect of estrogens on the hepatic synthesis of proteins.

A more interesting effect of oral contraceptive treatment is the shortening of euglobin lysis time that was measured at the end of local venous occlusion. An increase in the fibrinolytic potential may be considered a "protective" phenomenon resulting from oral contraceptives acting by either increasing the production of tissue plasminogen activator or depressing the production of its specific inhibitor. Whether this phenomenon is compromised in some subjects may be an important question to solve to detect women at risk of thrombotic events.

Finally, it must be emphasized that the results reported here were obtained in young healthy, nonsmoking women and were devoid of any clinical meaning. That does not imply that in other women with unknown lesions of the vessel wall or local disturbances of blood circulation, such as venous stasis or turbulences, individual marked alterations in hemostasis might not increase the thrombotic risk.

Effects of long-term gestodene-containing oral contraceptive administration on hemostasis

Rosanna Abbate, MD, Stefania Pinto, MD, Carlo Rostagno, MD, Vincenzina Bruni, MD, Daniela Rosati, MD, and Guglielmo Mariani, MD

Florence, Italy

The purpose of this study was to evaluate the behavior of the hemostatic system during treatment with gestodene-containing oral contraceptives in monophasic (SHD 356, $n = 15$) and triphasic (SHD 415, $n = 15$) formulations. No changes in platelet (β-thromboglobulin, platelet aggregate ratio, and megathrombocyte) and routine clotting assays were observed. Factor VIIc/factor VIIag ratio and fibrinopeptide A values showed a significant ($p < 0.005$) increase after three cycles of both treatments. A slight, significant increase ($p < 0.01$) in antithrombin III activity was observed during triphasic treatment. Protein C was unchanged. Fibrinolytic activity and plasminogen levels were significantly increased ($p < 0.05$ and $p < 0.001$). After 6 and 9 months, the factor VIIc/factor VIIag ratio was still significantly enhanced, whereas fibrinopeptide A values significantly ($p < 0.05$) decreased, even if they were higher ($p < 0.05$) than basal values. The persistence of factor VII activation without enhanced thrombin formation after long-term use of oral contraceptives suggests that at that time the activity of antithrombotic mechanisms counteracts the prothrombotic tendency, thus helping to minimize unwanted side effects on hemostasis during long-term drug administration. (Am J Obstet Gynecol 1990;163:424-30.)

Key words: Gestodene, oral contraceptives, blood clotting, fibrinopeptide A, factor VII

Fibrin formation in vivo is modulated by two mechanisms, the blood clotting inhibitory system, which inactivates serine proteases and nonenzymatic cofactors, and the fibrinolytic system, which removes fibrin deposition. The relevant role of these physiologic regulatory mechanisms is supported by the increased occurrence of thromboembolic complications in inherited disorders with impairement of these antithrombotic activities.[1-3]

The use of oral contraceptives has been demonstrated to affect the hemostatic system, inducing an increase in procoagulant factor activities and a simultaneous decrease in the levels of the naturally occurring coagulation inhibitor, antithrombin III.[4, 5] These changes in the hemostatic system may at least partially account for the higher incidence of thrombotic disease associated with oral contraceptive treatment.[6]

In recent years the introduction of low-dose estrogen formulations has notably decreased the magnitude of changes in procoagulant and antithrombin III activity.[7-9] Moreover, with low-dose oral contraceptives, an increase in fibrinolytic activity has been found,[10] thus contributing to a reduced risk of thromboembolism.[11]

Previous reports by us[12, 13] on treatment with the recently developed combination of ethinyl estradiol and gestodene showed limited hemostatic changes. Gestodene is a novel progestogen of greater biologic activity than levonorgestrel, and it can be used in very low-dose oral contraceptives.[14]

The purpose of this longitudinal investigation was to assess blood clotting activation (fibrinopeptide A and factor VII) and the behavior of both physiologic inhibitors, antithrombin III and protein C, and the fibrinolytic system during long-term administration of ethinyl estradiol–gestodene in monophasic and triphasic formulations.

Material and methods

Subjects. Thirty healthy women, ages 17 to 45 years, were randomly allocated to receive nine treatment cycles of ethinyl estradiol–gestodene in monophasic (SHD 356, $n = 15$) or triphasic (SHD 415, $n = 15$) formulations.

The following inclusion criteria were used: no history of thrombotic disease or varices, normal dietary and life habits, not overweight, no pregnancy or oral contraceptive treatment for at least 9 months, and smoking habits of no more than 10 cigarettes per day. The two groups were comparable for age, weight, and life and smoking habits.

The monophasic formulation (SHD 356) contained 30 μg of ethinyl estradiol and 75 μg of gestodene. The triphasic formulation (SHD 415) contained six tablets of 30 μg of ethinyl estradiol + 50 μg of gestodene, five

tablets of 40 μg of ethinyl estradiol + 70 μg of gestodene, and 10 tablets of 30 μg of ethinyl estradiol + 100 μg of gestodene.

Blood samples were taken before treatment was started and between days 25 and 28 of treatment during the first, third, sixth, and ninth cycles from subjects fasting overnight.

Subjects were free from any other drug in the 2 weeks preceding blood sampling.

Methods. Platelet and megathrombocyte counts were performed in whole blood by the platelet analyzer 810 (Baker Instruments, Allentown, Pa.). Platelet aggregate ratio was carried out according to Wu and Hoak.[15] β-Thromboglobulin concentration was measured in platelet-poor plasma by radioimmunoassay (Amersham International, United Kingdom) according to Ludlam and Cash.[16] Fibrinopeptide A was measured in platelet-poor plasma by radioimmunoassay with a kit purchased from Mallinckrodt Inc. (St. Louis, Mo.), according to Hofmann and Straub.[17] Factor VII clotting activity was performed in plasma by one-stage clotting assay with human brain thromboplastin.[18] Factor VII antigen was measured by immunoenzymatic assay (enzyme-linked immunoassay, Stago, Asnieres sur Seine, France).[19] Antithrombin III activity was assayed by the amidolytic method[20] by means of automated equipment (Allied Instrumentation Laboratory, Milan, Italy). Protein C was measured by coagulant assay (Behringwerke, Marburg, Federal Republic of Germany).[21] Spontaneous plasma fibrinolytic activity was assayed by euglobulin clot lysis time and was expressed as fibrinolytic units, which were obtained by dividing 1300 by lysis time (minutes).[22] Plasminogen assay was performed by the amidolytic method[23] with automated equipment (Allied Instrumentation Laboratory). Routine blood clotting tests (fibrinogen, activated partial thromboplastin time, and prothrombin time) were performed.

Statistical analysis. Results are expressed as mean ± standard deviation (SD).

Statistical analysis was carried out with the Student *t* test for paired data.

Results

During both treatments, no significant differences in platelet and megathrombocyte counts, circulating platelet aggregates, and β-thromboglobulin plasma levels (Table I and Table II) were observed.

Fibrinopeptide A plasma levels increased throughout the study after only one cycle of both treatments (Table III). The maximum increase was observed after the first cycle during monophasic treatment ($p < 0.001$) and after the third cycle during triphasic treatment ($p < 0.005$).

At subsequent observations, fibrinopeptide A values showed a tendency to decrease; after nine cycles of monophasic treamtent, fibrinopeptide A levels were significantly ($p < 0.05$) lower compared with first cycle values. After six and nine cycles of triphasic treatment, fibrinopeptide A levels significantly ($p < 0.05$) decreased compared with third cycle values, even if they were still significantly higher than baseline values ($p < 0.05$).

Factor VII clotting activity and factor VII antigen rose during the treatments, but the increase in factor VII clotting activity was greater than that of factor VII

antigen, so that the factor VII clotting activity/factor VII antigen ratio was significantly enhanced at all cycles investigated (Table IV).

Antithrombin III activity showed no significant changes during monophasic treatment (Table V). During triphasic treatment, antithrombin III activity was unmodified after the first cycle, whereas a slight but significant increase was observed at cycles 3 and 6. After nine cycles, antithrombin III activity was not statistically different from baseline values (Table V).

Protein C, assayed as functional activity, was unaltered throughout the study during both treatments (Table VI).

Fibrinolytic activity, which was evaluated as euglobulin clot lysis time, and plasminogen concentration significantly increased after only the first cycle of both pill administrations and remained elevated throughout the treatment period (Tables VII and VIII).

No changes in fibrinogen, activated partial thromboplastin time, and prothrombin time were observed (data not shown).

Comment

Our findings indicate that during the administration of both ethinyl estradiol–gestodene formulations, some prothrombotic changes take place. Significant blood clotting activation occurs during the first months of both treatments as indicated by increased levels of fibrinopeptide A, which provides reliable evidence of increased thrombin generation in vivo. In fact fibrinopeptide A represents the first fragment split from fibrinogen by trace amounts of thrombin.[24] The blood clotting activation that was observed in this study seems small because no changes in platelet functions were found, thus indicating that thrombin generation did not reach the amount (0.01 IU/ml) needed to trigger platelet activation.[25] The rise in fibrinopeptide A levels was similar in magnitude and time course to that found during the administration of low-dose treatment with levonorgestrel[8] and cyproterone acetate,[9] and it was notably smaller than that observed with the 50 μg estrogen formulation.[26]

In this study we have investigated the factor VII clotting activity/factor VII antigen ratio for the assessment of a hypercoagulable state. In fact, the study of factor VII provides notable insight into its particular characteristics in the regulation and initiation of coagulation.[27, 28] During the two treatments, both factor VII clotting activity and factor VII antigen were increased, but there was a greater rise in factor VII clotting activity compared with factor VII antigen. The enhancement of the factor VII clotting time/factor VII antigen ratio

suggests that an increase in the functional activity of factor VII rather than only an increase in its concentration occurs.

The enhancement of factor VII clotting activity during pill administration could be attributed to the activation of factor VII by factor XII, which has been found to be increased after oral contraceptive administration.[29, 30] Oral contraceptives are known to modify the lipoprotein pattern, inducing an increase in very low–density lipoprotein and chylomicron levels.[31] The negative charges of these lipoproteins have been demonstrated to interact with factor XII, facilitating its conversion into its active conformation,[32, 33] which, in turn, can promote factor VII activation.

During the first three cycles of therapy, the increase in the factor VII clotting activity/factor VII antigen ratio was associated with coagulation activation, as demonstrated by a rise in fibrinopeptide A levels. Subsequently, even if the enhancement of factor VII clotting activity/factor VII antigen subsided, thrombin production showed a significant decrease, thus indicating that no further increase in blood clotting activation occurs, even if the prothrombotic stimulus persists.

In our study we observed a significant increase in fibrinolytic activity and plasminogen levels. The increase in plasminogen activity could be caused by decreased levels of histidine-rich-glycoprotein during low-dose oral contraceptive treatment.[34] In fact, histidine-rich glycoprotein binds to the high-affinity lysine-binding sites of plasminogen and interferes with the binding of plasminogen to fibrin.[35]

In conclusion, the physiologic antithrombotic mechanisms, antithrombin III, protein C, and the fibrinolytic system, counteract the coagulant tendency observed during low-dose ethinyl estradiol–gestodene treatment, thus helping to minimize unwanted side effects on hemostasis during long-term drug administration.

Comparative studies of 30 μg ethinyl estradiol combined with gestodene and desogestrel on blood coagulation, fibrinolysis, and platelets

Leisha Daly and John Bonnar, MD, FRCOG
Dublin, Ireland

An association between an increase in the incidence of thromboembolic disease and the use of combined oral contraceptives has been shown by several epidemiologic studies. Evidence of the vascular complications of oral contraceptives suggests that venous thromboembolism correlates with estrogen dosage and arterial complications with both estrogen and progestogen components. In 60 healthy, randomly allocated women, the effects of ethinyl estradiol, 30 μg, combined with gestodene, 75 μg, and desogestrel, 150 μg, on blood coagulation, fibrinolysis, and platelet function were compared. Subjects were studied before oral contraceptive use, at 12, 24, 36, and 48 weeks of treatment, and at 6 and 12 weeks after treatment. Both oral contraceptives affected the hemostatic system, but our results indicate that the ethinyl estradiol/gestodene combination causes changes in the hemostatic system similar to those in the ethinyl estradiol/desogestrel combination. Factors VII and X activity were slightly higher with the ethinyl estradiol/desogestrel combination than with the ethinyl estradiol/gestodene combination, possibly reflecting a greater estrogenic effect. (AM J OBSTET GYNECOL 1990;163:430-7.)

Key words: Oral contraceptives, coagulation, fibrinolysis, dosage of estrogen, type of progestogen

Since the introduction of oral contraceptives in the early 1960s, several epidemiologic studies have reported an association between their use and an increased risk of vascular disease. The main vascular complications are venous thromboembolic disease, myocardial infarction, and hemorrhagic and thrombotic strokes.[1-5] This risk appears to have decreased in parallel with a reduction in the estrogen content.[6-8] The progestogen component of the pill modifies the estrogen effects on blood coagulation[9,10] and may contribute to the increased risk of stroke and ischemic heart disease.[10-12] New formulations of oral contraceptives have recently been introduced containing low doses of estrogen in combination with new progestogens. This study is designed to examine the effects of two new combined oral contraceptives on blood coagulation, fibrinolysis, and platelet function. These pills contain 30 μg of ethinyl estradiol, in combination with gestodene or desogestrel, in monophasic formulations.

Material and methods

Subjects. Sixty healthy women who were between the ages of 18 and 34 years with no contraindications to estrogen/progestogen therapy took part in the study. Women who smoked 15 cigarettes or more per day were excluded. Subjects were randomly allocated to two groups: (1) group 1: 30 women taking Femodene, containing 30 μg of ethinyl estradiol + 75 μg of gestodene, 21 tablets per cycle, and (2) group 2: 30 women taking Marvelon, containing 30 μg of ethinyl estradiol + 150 μg of desogestrel, 21 tablets per cycle.

Method and timing of blood collection. Venous blood specimens were taken between 10:00 AM and noon each morning in the control cycle and thereafter at 12, 24, 36, and 48 weeks of treatment and at 6 and 12 weeks after hormone treatment. In the pretreatment cycle, blood samples were taken between days 21 and 24 of the cycle. In the treatment cycles blood samples were taken between days 15 and 21 of tablet administration.

Laboratory methodology. Prothrombin time,[13] activated thromboplastin time,[14] factor VII activity,[15] and fibrinogen[16] were assayed by standard laboratory techniques. Specific chromogenic substrates were used to assay plasminogen,[17] antithrombin III,[18] factor X,[19], anti-Xa,[20] and antiplasmin.[21] Plasminogen activator was measured by means of the euglobulin precipitate and the fibrin plate technique.[22] The Chandler tube method[23] was used to measure thrombin-induced platelet aggregation, and platelets were counted with a Thrombocounter-C.[24] Prothrombin clotting time, factor VII, activated thromboplastin time, platelet aggregation, platelet count, and fibrin plate assay were car-

6/0/17865

ried out within 1 hour of venipuncture. Factor X, anti-Xa, antiplasmin, plasminogen, antithrombin III, and fibrinogen were assayed on fresh-frozen plasma stored at −20° C.

Statistical analysis. The null hypothesis was that both oral contraceptives were equal with respect to the hemostatic parameters that were measured. The alternative hypothesis was that with a sample size of 30 women in each treatment group, a type I error of $\alpha = 0.05$, and a test power of $1 - \beta = 0.90$, a t test would detect a difference of $\Delta = 0.8^* \sigma$. The maximal increase or minimal decrease in the treatment phase was analyzed with an analysis of covariance (covariate = prevalue of the appropriate variable, dependent variable = maximal increase or minimal decrease at $\alpha = 0.05$). Similarly, the values of 12 weeks after treatment were analyzed with an analysis of covariance with the prevalues as covariate at $\alpha = 0.05$. Descriptive statistics (average, minimum, maximum, percentage averages, and box plots) (Fig. 1) were computed for all variables. Student t tests were used to determine the level of significance of the observed changes within the groups.

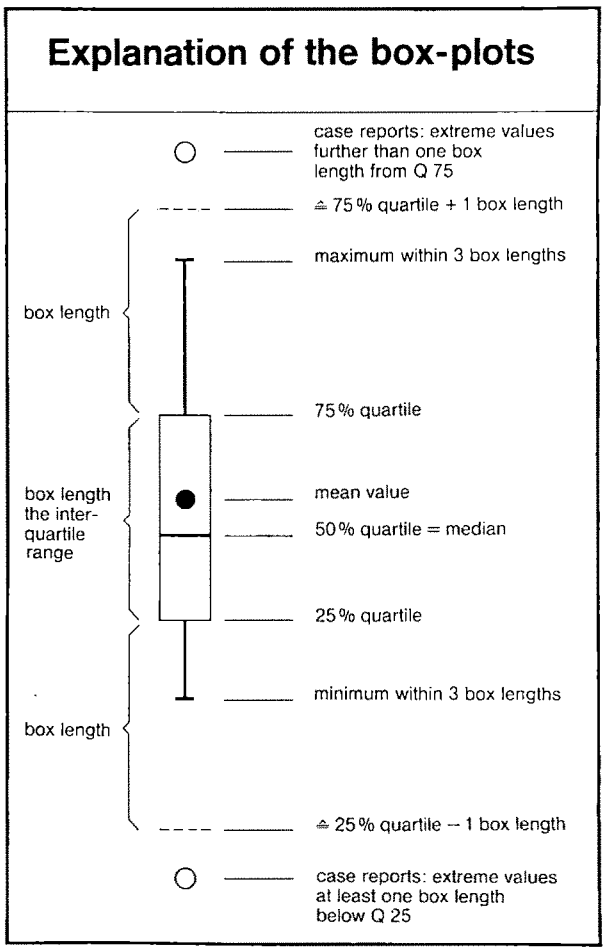

Fig. 1. Description of box plots.

Results

Coagulation system

Prothrombin time. There was no observable difference between treatments in the treatment and posttreatment phases ($p > 0.05$). The maximal increase has a positive slope $\beta = 0.05$; Fig. 2 shows a stable progression of the average time curve.

Activated partial thromboplastin time. There were no observable differences between treatments in the treatment and posttreatment phases ($p > 0.05$). The maximal increase over the treatment phase has a negative slope $\beta = -0.17$; Fig. 3 shows a slight decrease in the average time curve.

Factor VII. Factor VII clotting time was decreased at 12, 24, 36, and 48 weeks in women taking either the desogestrel or the gestodene combination, which indicated an increase in factor VII activity ($p < 0.001$); the decrease was slightly greater in those women taking the desogestrel combination. There was no observable difference between treatments in the treatment and posttreatment phases ($p > 0.05$). The maximal increase over the treatment phase has a positive slope $\beta = 0.34$ ($p < 0.05$), but Fig. 4 shows a decrease in the average time curve.

Factor X. Factor X was increased at 12, 24, 36, and 48 weeks of treatment when compared with pretreatment levels in both groups ($p < 0.001$); the increase was slightly greater in the desogestrel group. Factor X activity 6 weeks after treatment was decreased from that at 48 weeks while receiving treatment. There was no observable difference between treatments in the treatment phase ($p > 0.05$), but 12 weeks after treatment there was a difference between the two treatment groups ($p < 0.05$). The level of factor X for the desogestrel group was higher than that for the gestodene group. The maximal increase over the treatment phase has a positive slope $\beta = 0.14$; Fig. 5 shows a slight increase in the average time curve.

Antithrombin III. Antithrombin III levels were decreased at 36 weeks in women taking either combination ($p < 0.01$). At 6 weeks after treatment, the antithrombin III levels of both groups had returned to within the normal range. There were no observable differences in antithrombin III levels between treatments in the treatment and posttreatment phases ($p > 0.05$). The minimal decrease over the treatment phase has a positive slope $\beta = 0.38$; Fig. 6 shows a stable progression of the average time curve.

Anti-Xa. There was no observable difference between treatments in the treatment and posttreatment phases ($p > 0.05$). The minimum decrease over the treatment phase has a negative slope $\beta = -0.11$; Fig. 7 shows a slight decrease in the average time curve.

Fibrinolytic system

Plasminogen. Plasminogen levels at 12, 24, 36, and 48

weeks were increased by both pills ($p < 0.001$). There was a difference between treatments in the treatment phase ($p < 0.05$), and there was no difference between treatments 12 weeks after treatment ($p > 0.05$). The plasminogen level was higher in the gestodene group than in the desogestrel group. The maximal increase over the treatment phase has a positive slope $\beta = 0.08$; Fig. 8 shows a slight increase in the average time curve.

Antiplasmin. There was no observable difference between treatments in the treatment phase ($p > 0.05$), but there was a difference between the two treatment groups 12 weeks after treatment ($p < 0.05$). The antiplasmin level was higher in the desogestrel group than in the gestodene group. The maximal increase over the treatment phase has a negative slope $\beta = -0.33$; Fig. 9 shows a slight decrease in the average time curve.

Fibrinogen. Fibrinogen levels increased with both pills ($p < 0.01$) and returned to pretreatment levels after treatment. There was no observable difference between treatments in the treatment and posttreatment phases ($p > 0.05$). The maximal increase over the treatment phase has a positive slope $\beta = 0.24$; Fig. 10 shows a slight increase in the average time curve.

Fibrinolytic activity. Fibrinolytic activity increased from 12 weeks on treatment in both groups ($p < 0.001$). During treatment increased fibrinolytic activity was sustained and rapidly returned to pretreatment levels 6 weeks after the pill was stopped. There was no observable difference between treatments in the treatment and posttreatment phases ($p > 0.05$). The maximal increase over the treatment phase has a positive slope

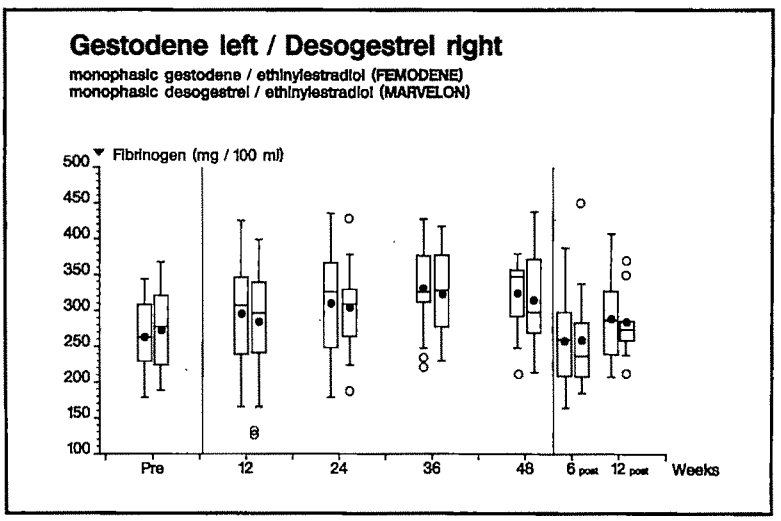

Fig. 10. Effects of gestodene and desogestrel on fibrinogen.

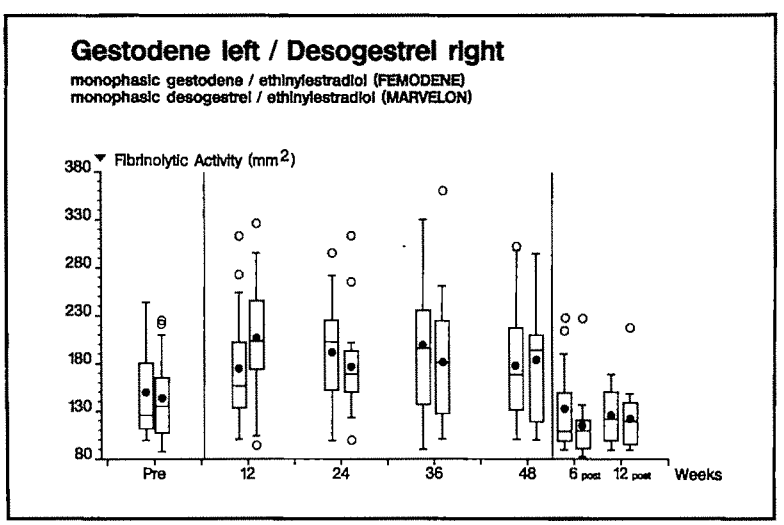

Fig. 11. Effects of gestodene and desogestrel on fibrinolytic activity.

$\beta = 0.22$; Fig. 11 shows a slight increase in the average time curve.

Platelets

Platelets aggregation. Platelet aggregation was decreased in both groups and the decrease was greater in the desogestrel group ($p < 0.001$) than in the gestodene group ($p < 0.01$). There was no observable difference between treatments in the treatment and posttreatment phases ($p > 0.05$). The minimal decrease over the treatment phase has a slope $\beta = 0.20$, but Fig. 12 shows a slight decrease in the average time curve.

Platelet count. There was no observable difference between treatments in the treatment and posttreatment phases ($p > 0.05$). The maximal increase over the treatment phase has a slope $\beta = 0.00$; Fig. 13 shows a stable progression in the average time curve.

Comment

The new low-dose estrogen/progestogen oral contraceptives induce major changes in the coagulation and fibrinolytic systems and in platelet function. The prothrombin time and activated partial thromboplastin time, which measure the overall activity of the extrinsic and intrinsic coagulation pathways, respectively, showed no significant changes with both oral contraceptive formulations. This indicates that the overall effects of the new pills are less than what occurs with the 50 μg pills that induce significant changes in these tests.[9] Likewise, changes in the coagulation system with respect to factor X, antithrombin III, and platelet aggregation are not as marked with the new low-dose monophasic oral contraceptives as with those previously studied that contained 50 μg of estrogen.[10] Both estro-

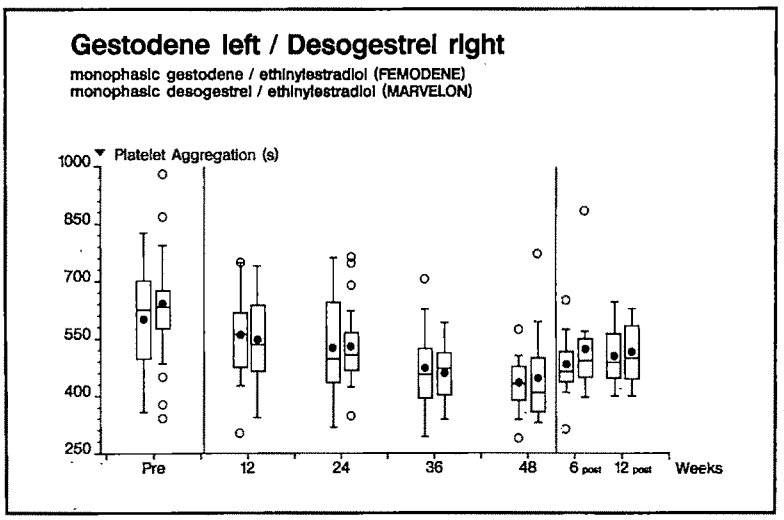

Fig. 12. Effects of gestodene and desogestrel on platelet aggregation.

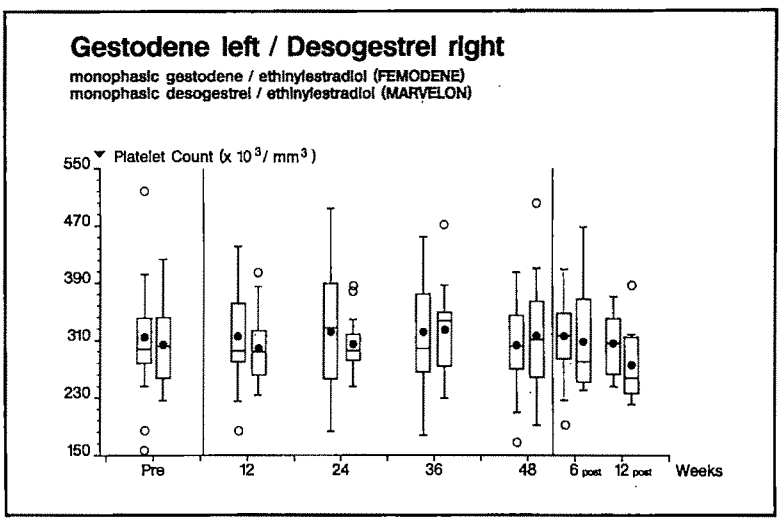

Fig. 13. Effects of gestodene and desogestrel on platelet count.

gen/progestogen pills increased significantly the activity or factors VII and X, and the greater increase with the desogestrel pill suggests this combination has a greater estrogenic effect. Plasminogen and fibrinolytic activity were markedly increased by both hormonal preparations, and this enhancement of fibrinolysis is likely to counteract the increase in fibrinogen and coagulation activity that protects the dynamic balance between coagulation and fibrinolysis. Platelet aggregation was decreased by both pills and more so by the desogestrel combination. This would seem to be an undesirable effect.

The low-dose oral contraceptives with the new progestogens studied induce marked changes in the hemostatic system, in particular, enhanced activity of factors VII and X and acceleration of platelet aggregation. These changes in the physiology of hemostasis suggest that these new pills will also carry a thrombogenic hazard in susceptible women. The effects on hemostasis arise from the overall estrogenic activity, which is determined by the progestogen used in combination with the estrogen. More research is required to find whether effective combinations can be obtained that will induce fewer changes in the hemostatic system and other physiologic processes. Meantime, it would be unwise for any claims to be made that oral contraceptives with the new progestogens, gestodene and desogestrel, will be free of vascular complications.

We acknowledge the technical help of Lucy Norris and the detailed supervision of the women carried out by research nurses, Eilis Carroll and Bernadette Hennelly. We also thank the women who kindly agreed to

take part in this study and Dr. T. Louton of the Statistics Department, Schering AG, Berlin, who kindly carried out the analysis of covariance and prepared the box plots.

Enhanced generation and resolution of fibrin in women above the age of 30 years using oral contraceptives low in estrogen

Jørgen Gram, MD, DSc, Steffen Munkvad, MD, and Jørgen Jespersen, MD, DSc
Esbjerg, Denmark

Epidemiologic studies have suggested a relationship between the use of oral contraceptives and mortality from cardiovascular diseases in older women. Therefore we studied generation and resolution of fibrin in 28 healthy women above age 30 years, using oral contraceptives containing 30 to 50 μg of ethinyl estradiol. Thirty healthy nonusers served as control subjects. The oral contraceptive group had increased plasma concentration of thrombin–antithrombin III complexes ($p < 0.01$), which indicated an enhanced generation of thrombin, increased plasma activity of tissue-type plasminogen activator ($p < 0.01$), decreased plasma activity of plasminogen activator inhibition ($p < 0.01$), and increased plasma concentration of fibrin degradation products ($p < 0.04$). Interestingly, the ratio of thrombin–antithrombin III complexes/fibrin degradation products did not deviate significantly between groups. Twelve of the 28 women using oral contraceptives were light smokers, that is, less than 15 cigarettes per day. There were no differences in the determined variables between smokers and nonsmokers. Our study suggests that healthy women older than 30 years who use oral contraceptives containing 30 to 50 μg of ethinyl estradiol have an enhanced generation and resolution of fibrin, while the hemostatic balance is unaltered. These findings are unaffected by moderate cigarette smoking. (Am J Obstet Gynecol 1990;163:438-42.)

Key words: Oral contraceptives, tissue-type plasminogen activator, coagulation, fibrin degradation products

The results of epidemiologic studies have indicated that women taking oral contraceptives have an increased risk of cardiovascular disease.[1-4] A further stratification of the epidemiologic results suggests that the risk of thrombosis is particularly linked to older oral contraceptive users.

One of the most important concepts regarding the risk of thrombosis in users of oral contraceptives concerns a defective hemostasis.[5,6] An enhanced formation of fibrin caused by an active coagulation or a defective fibrinolysis might result in a state of clinical thrombosis.[5] Thus it is well known that the use of oral contraceptives should be avoided in women with congenital errors in the inhibition of coagulation, such as antithrombin III, protein C, or protein S deficiencies.[7-9] Less clinical information has been obtained from studies on fibrinolysis.

We have studied the activation of coagulation and fibrinolysis in healthy women with an apparently increased risk of thrombosis, that is, women older than 30 years, who use oral contraceptives low in estrogen.

Table I. Clinical characteristics in 28 healthy women receiving oral contraceptives (oral contraceptive group) low in estrogen (30 to 50 μg of ethinyl estradiol) and in 30 healthy women (control group); medians and ranges are shown

	OC group	*Control group*
Age (yr)	42 (31-48)	41 (31-49)
Weight (kg)	62 (52-85)	66 (53-96)
Systolic BP (mm Hg)	130 (115-150)	130 (40-170)
Diastolic BP (mm Hg)	80 (75-95)	85 (80-100)
Smokers *(n)*	12	14

OC, Oral contraceptive; *BP*, blood pressure.

By means of new specific assays, we could obtain information of the in vivo generation of thrombin and resolution of fibrin. In addition, we studied in more details the activation and inhibition of tissue-type plasminogen activator.

Material and methods

Subjects. Twenty-eight healthy women above the age of 30 years using low-dose oral contraceptives (30 to 50 μg of ethinyl estradiol) for at least 3 months were involved in the study (oral contraceptive group). Serving as controls were 30 healthy women above the age of 30 years, who had not taken any drugs (control group). The two groups of women were comparable

Table II. Hemostatic variables (medians and 25 to 75 interpercentile ranges) in 28 healthy oral contraceptive users stratified as light smokers (<15 cigarettes/day) and nonsmokers

	Smokers (n = 12)	*Nonsmokers (n = 16)*
TAT complexes (μg/L)	3.3 (3.1-4.2)	3.5 (2.6-4.9)
t-PA activity (mm^2)	34 (26-38)	34 (17-45)
PAI activity (IU/ml)	4.0 (2.7-6.1)	5.4 (4.9-6.7)
FbDP (μg/ml)	0.27 (0.17-0.33)	0.22 (0.17-0.24)
TAT complexes/FbDP ($\times 10^{-3}$)	17.1 (9.6-25.8)	16.2 (13.0-21.2)

with respect to age, weight, systolic and diastolic blood pressures, and the number of light smokers, that is, less than 15 cigarettes per day (Table I).

Blood collection and preparation. Blood samples were collected in the morning between 8:00 and 9:00 AM between days 11 and 14 in the menstrual cycle from fasting individuals. Samples were anticoagulated with trisodium citrate (4.5 ml blood; 0.5 ml 0.13 mol/L trisodium citrate) and tripotassium ethylene diamine tetraacetate (30 ml blood; 0.06 ml 0.17 mol/L EDTA). The blood sampling, the preparation of plasma samples, and the handling of the specimens followed standardized procedures.[10]

Assays. As a measure of in situ generation of thrombin, we determined thrombin–antithrombin III complexes by means of a commercially available enzyme-linked immunoassay method (Behringwerke, Marburg, West Germany) and expressed the results in μg/L according to a calibrator solution delivered by the manufacturer.[11] The plasma activities of the tissue-type plasminogen activator were determined on fibrin plates by the use of a standardized technique[12] and the results expressed as mm^2. The plasma activities of the plasminogen activator inhibition were determined by addition to the plasma samples of human two-chain melanoma tissue-type plasminogen activator (Organon Teknika, Turnhout, Belgium) as previously described[13] and the results expressed as IU/ml calibrated against the international standard preparation (Lot No. 83/517[14]). The plasma concentrations of fibrin degradation products were determined by a commercially available enzyme-linked immunoassay method (Organon Teknika) and the results expressed as μg/ml according to a calibrator delivered from the manufacturer. It should be noted that the antibodies used in the fibrin degradation product assay did not cross-react with fibrinogen degradation products.[15]

Statistical methods. Significant differences between the two groups of women were evaluated by means of the Mann Whitney test and Fisher's exact test. The individual data, medians, and quartiles are presented in the illustrations.

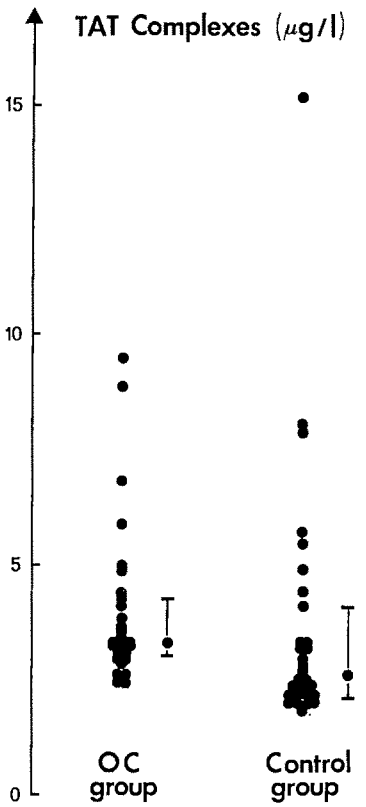

Fig. 1. Individual plasma concentrations of thrombin–antithrombin III *(TAT)* complexes (μg/L) in 28 healthy women taking oral contraceptives low in estrogen (OC group) and in 30 healthy women (control group). Median and 25 to 75 interpercentile ranges are indicated. Concentrations of thrombin–antithrombin III complexes were significantly higher in the oral contraceptive group ($p < 0.01$).

Results

The plasma concentrations of thrombin–antithrombin III complexes (Fig. 1) were significantly increased in the oral contraceptive group compared with nonusers ($p < 0.01$). Similarly, the plasma activities of tissue-type plasminogen activator were significantly increased ($p < 0.01$) and the plasma activities of plasminogen activator inhibition were significantly depressed ($p < 0.01$) in the oral contraceptive group compared with the control group (Fig. 2). Consistent with these latter results we observed significantly increased plasma concentrations of fibrin degradation products (Fig. 3) in the oral contraceptive group compared with nonusers ($p < 0.05$).

When we determined the ratio of thrombin–

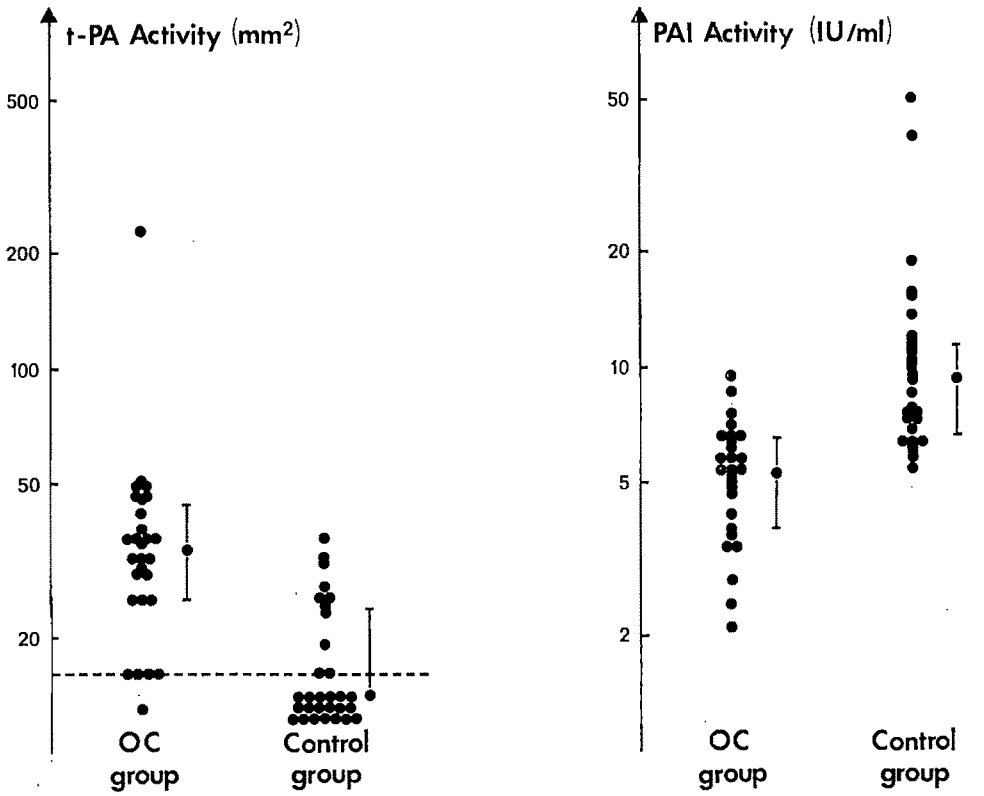

Fig. 2. Individual activities in plasma euglobulins of tissue-type plasminogen activator *(t-PA; left panel)* expressed as mm^2 (log scale; the detection limit of the fibrinogen batch used indicated by *horizontal broken line*) and plasminogen activator inhibition *(PAI; right panel)* expressed as IU/ml in 28 healthy women receiving oral contraceptives low in estrogen (OC group) and in 30 healthy women (control group). Medians and 25 to 75 interpercentile ranges are indicated. Activities of tissue-type plasminogen activator were significantly increased ($p < 0.01$), and activities of plasminogen activator inhibition significantly depressed ($p < 0.01$) in the oral contraceptive group.

antithrombin III complexes/fibrin degradation products (Fig. 4), a calculated measure of the actual, dynamic state of the hemostatic balance in an individual, we found no significant deviations between the two groups.

Twelve of the 28 women using oral contraceptives were light smokers, that is, less than 15 cigarettes per day, whereas the remaining 16 women were nonsmokers (Table I). When we compared the plasma levels of thrombin–antithrombin III complexes, tissue-type plasminogen activator activity, plasminogen activator inhibition activity, fibrin degradation products and the ratio of thrombin–antithrombin III complexes/fibrin degradation products between these two groups, we found no significant differences (Table II).

Comment

In accordance with conclusions from previous studies on the effect of oral contraceptives on the hemostatic system,[5, 6, 16-22] the present study indicates that oral contraceptives containing 30 to 50 μg of ethinyl estradiol induces significant changes in components involved in the activation of coagulation and fibrinolysis. We have observed increased plasma concentrations of thrombin–antithrombin III complexes (Fig. 1), increased plasma activities of tissue-type plasminogen activator (Fig. 2), decreased plasma activities of plasminogen activator inhibition (Fig. 2), and increased plasma concentrations of fibrin degradation products (Fig. 3) compared with control subjects. As a supplement to previous studies, these findings strongly suggest that the use of low-dose oral contraceptives in healthy women causes an enhanced generation of thrombin, an enhanced formation of fibrin, and an enhanced resolution of fibrin. However, using molecular markers for the evaluation of the relative activation of coagulation (thrombin–antithrombin III complexes) and fibrinolysis (fibrin degradation products), we found that the ratio of thrombin–antithrombin III complexes/fibrin degradation products did not deviate significantly between oral contraceptive users and control subjects (Fig. 4). These findings indicate a more rapid

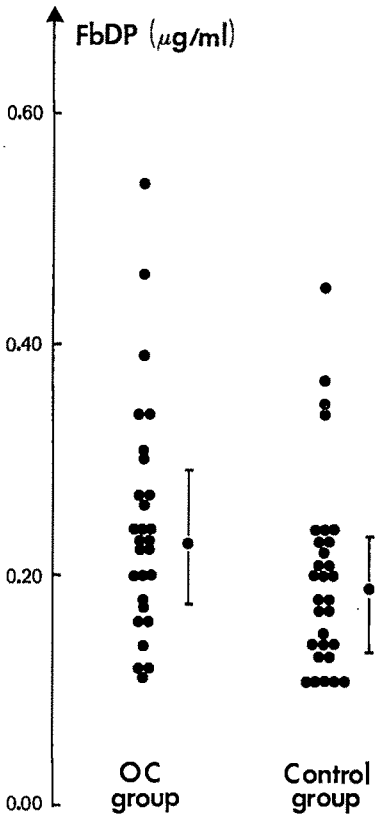

Fig. 3. Individual plasma concentrations of fibrin degradation products *(FbDP)* in 28 healthy women receiving oral contraceptives low in estrogen (OC group) and in 30 healthy women (control group). Medians and 25 to 75 interpercentile ranges are indicated. Concentrations of fibrin degradation products were significantly increased in the oral contraceptive group ($p < 0.05$).

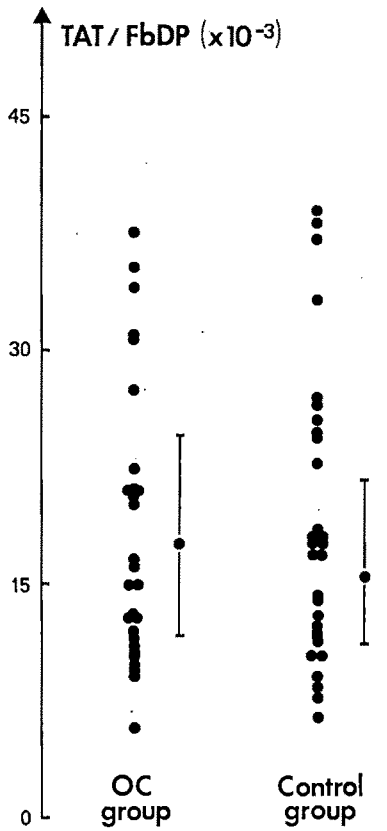

Fig. 4. Individual ratio of thrombin–antithrombin III complexes/fibrin degradation products *(TAT complexes/FbDP)* in 28 healthy women receiving oral contraceptives low in estrogen (OC group) and in 30 healthy women (control group). Medians and 25 to 75 interpercentile range are indicated. There was no significant difference between the two groups.

turnover of fibrinogen/fibrin among oral contraceptive users, whereas the balance between activation of coagulation and fibrinolysis is not significantly affected. Thus our study may help to explain the very low overall incidence of thromboembolic events in women using oral contraceptives despite obvious biochemical changes in individual components involved in hemostasis. It should be noted that light cigarette smoking, that is, less than 15 cigarettes per day, did not significantly affect changes in activation and fibrinolysis induced by oral contraceptives (Table II). This observation is compatible with a recent epidemiologic follow-up study,[23] which suggests a very moderate increased risk of cardiovascular death in oral contraceptive users smoking less than 15 cigarettes per day.

Although the observations reported here do not definitely explain the apparent association between the risk of thrombosis and the consumption of oral contraceptives, they point to the absence of an increased risk with respect to the effect on the hemostatic balance in normal women. The use of molecular markers in future studies would help elucidate whether a risk group is characterized by an enhanced generation of thrombin or a defective resolution of fibrin.

PERSONAL, PRACTICAL ASPECTS SEEN FROM THE FAMILY PLANNING CLINIC'S POINT OF VIEW

Oral contraceptives in risk groups: Exclusion or monitoring?

John Guillebaud, MD
London, England

Careful consideration of absolute and relative contraindications, including newly appreciated factors such as past pregnancy-related hypertension, is essential to select what is termed the "safer women." A family history of either arterial or venous thrombosis indicates preliminary blood analysis to exclude atherogenic lipid states and thrombophilias. The goal then is to prescribe "safer pills." One should also allow for biologic variation in pharmacokinetics and end-organ responses. This can be done to a limited extent in clinical practice by using bleeding from the uterus as a "threshold bioassay." Namely, by identifying for each woman the lowest dose of a chosen estrogen-progestogen combination that is just sufficient to prevent breakthrough bleeding. Thereafter, monitoring requires attention to the development of new risk factors, regular blood pressure checks, and specific attention to the important side effects of headaches and migraines, especially if there are focal (cerebral ischemic) symptoms. (Am J Obstet Gynecol 1990;163:443-6.)

Key words: Oral contraceptive risk factors, breakthrough bleeding, lipid and hemostatis variables, focal migraine, blood pressure

Despite 30 years of research, the area of epidemiology, which gives the most relevant data about beneficial and adverse effects, provides mainly information about yesterday's pills and is too imprecise a tool to distinguish between formulations. Consequently, we are forced to give more weight than is warranted to minor differences in the effects on metabolic variables.

There are many pitfalls. Are the differences (especially in cross-sectional studies) from the pills studied or the characteristics of the women using them because of factors such as prescriber bias? If truly pill related, we still do not know the health implications of most of the observed changes. In situations in which we believe that we do, we must look at the whole picture, consider hemostasis as well as lipids, and measure blood pressure and blood constituents. In comparing different formulations, we may find benefits that are mutually exclusive (e.g., relatively estrogen-dominant pills may appear better for lipids but worse for changes to the hemostatic system). The fact that *mean* alterations are within the normal range may be falsely reassuring for some individuals, who may have significant abnormalities before they first take the combined oral contraceptive or have a major change within the range.

In short, we badly need more large comparative studies with a defined power great enough to avoid missing real differences, separate analyses of the extreme percentiles, comparative studies with randomization to formulations containing the older and new progestogens, and all with good statistical analysis. Also important is clinical judgment, which gives appropriate weight to the findings compared with those from other research (e.g., into carcinogenesis).

In clinical practice it is impractical to perform complex laboratory tests on allcomers. Fortunately, however, it is probable that the metabolic differences between the currently recommended lowest dose oral contraceptives are relatively unimportant, and all are acceptable for the average woman requesting this method. More good can probably be done by careful prescribing and appropriate monitoring than by overattention to metabolic minutiae.

In selected cases laboratory tests become relevant. As will be described, the signal for arranging them is mainly careful identification of clinical risk factors from personal and family history.[1,2]

Prescribing summary

In using the scheme that follows, risk-benefit analysis must closely involve the woman, a woman-centered approach. After counseling many women will consider that the known benefits (contraceptive and noncontra-

Table I. Risk factors for cardiovascular system disease[1]

Risk factor	*Absolute contraindication*	*Relative contraindication*	*Remarks*
FH of CVS disease (arterial or venous) in a first-degree relative ≤45 yr	Known atherogenic lipid profile or prothrombogenic hemostatic profile or tests not available	Normal blood profiles or first attack in relative >45 yr	Normal blood if FH of arterial disease must test BOTH for lipids and hemostasis
DM	Severe or diabetic complications present (e.g., retinopathy)	Not severe/labile and no complications; young patient with short duration of DM	POP usually better choice hormone method
Raised BP	Systolic BP >160, diastolic BP >95 mm Hg, on repeated testing	Systolic 130-160; diastolic BP, 85-95 mm Hg	POP better choice
Cigarette smoking	>40 cigarettes/day	5-40 cigarettes/day	
Increasing age	>45 nonsmokers	35-45 non-smokers	Smokers should avoid/discontinue COCs 10 yr earlier
Excess weight	>50% above ideal for height	20%-50% above ideal	

Modified with permission. In: Filshie M, Guillebaud J, eds. Contraception science and practice. London: Butterworths, 1989:71.

FH, Family history; *CVS*, cardiovascular system; *DM*, diabetes mellitus; *POP*, progestogen-only pill; *BP*, blood pressure; *COC*, combined oral contraceptive.

Some of the numbers selected are necessarily a little arbitrary and relate to use of COCs solely for contraception.

Use of COCs for medical indications entails a different risk-benefit analysis, often more favorable to the use of the COC (see text).

Past personal history of any CVS disease/disorder associated with or predisposing to thrombosis (arterial or venous) always absolutely contraindicates the method.[1]

Synergism: Two or more relative contraindications signifies that the COC is absolutely contraindicated.

Recommendation on October 26, 1989, of Fertility and Maternal Health Drugs Advisory Committee to the FDA that there should be *no upper age limit* for COC use by *healthy nonsmoking* women makes age 45 years per se no longer an absolute contraindication.

ceptive) outweigh the known *and likely unknown* risks. Others will decide against the method in favor of an alternative, which is their prerogative.

The goal is to treat what I call the safer women with the safer pills. This involves answering four questions[2]:

1. Who never? (absolute contraindications)
2. Who usually not? (perhaps, but will special advice and monitoring—relative contraindications)
3. Which pill?
4. Which second choice of pill?

"The pill is reasonably safe: Some women are dangerous"

The absolute and relative contraindications to cardiovascular disease are listed in Table I; the remainder are described elsewhere.[1] Table I also suggests the point at which each of the recognized risk factors might pose sufficient risk on its own for the contraindication to be considered absolute rather than relative. The presence of two or more risk factors of a lesser degree implies synergism in decision making, which again is an absolute contraindication to the method in most cases.[1]

Family history of an arterial incident in a first-degree relative under age 45 years (especially a nonsmoker) indicates full blood lipid analysis (if available). Once identified, it is well accepted that preexisting atherogenic lipid profiles absolutely contraindicate the combined oral contraceptive for that individual.

Less developed in combined oral contraceptive prescribing practice and yet equally relevant is the concept of the thrombophilias. The most common of these prothrombotic congenital disorders are deficiencies in antithrombin III, protein C, or protein S. Together with rarer similar disorders so far characterized, they occur in about 1:2500 prospective pill takers[3] compared with a rate of about 1:500 for familial hypercholesterolemia.[4] Once again family history provides the clinical clue. An episode of venous or arterial thrombosis (more often the former) in a close relative under the age of 40 to 45 years indicates referral for investigation, ideally to a center capable of performing these tests. I believe that selective application of such specific tests to this relevant minority, chosen by family or personal history of thrombosis, would be more valuable than to arrange routine clotting tests or nonselective screening.

Migraine

Migraine is a specific risk factor for thrombotic stroke. In his monograph Bickerstaff[5] identified a group of young women admitted with strokes who had

Table II. Reasons to stop estrogen, pending advice

Symptoms	*Worst diagnosis or risk*
Pain	
In calf	DVT
In chest	PE, myocardial infarction
In abdomen	Thrombosis of major vessel
Dyspnea/hemoptysis	Pulmonary embolus
Migraine	
± Loss of visual field	Retinal thrombosis, impending stroke
± Unilateral numbness	Impending stroke
± Unilateral weakness	Impending stroke
± Dysphasia	Impending stroke
± Unexplained collapse	Impending stroke
BP ≥160/95	Hemorrhagic stroke
Immobilization after accident or emergency surgery	DVT/PE
Jaundice	Cholestasis or hepatitis

DVT, Deep venous thrombosis; *PE,* pulmonary embolus; *BP,* blood pressure.

had focal migraines. They had experienced attacks, during which lateralizing neurologic sypmtoms occurred attributable to transient cerebral ischemia (Table II). Estrogen in the combined pill was continued, and the transient ischemia tragically became permanent. A controlled trial would be unethical, and therefore prudence dictates that focal symptoms before or during pill taking should lead to discontinuation or permanent avoidance of the combined oral contraceptive in the future. The same applies to severe, sustained, or "crescendo" migraines. Diffuse migraine headaches, with which the women can live, may be considered a relative contraindication, provided that the woman is educated about the need to report any future transient ischemic symptoms[1] (Tables II and III).

Pregnancy-related hypertension (toxemia)

Croft and Hanneford[6] have recently shown from data derived from the British Royal College of General Practitioners' Study that a history of toxemia during pregnancy increased the risk of subsequent myocardial infarction (adjusted risk ratio, 2.8). If such women also smoked, the relative risk rose to 41. Use of the combined oral contraceptive had no multiplicative effect, and indeed current use of birth control pills increased the risk only among women who also smoked. Nevertheless, prudence dictates that any past history of severe pregnancy-related hypertension should be carefully noted. If combined with the risk factors in Table I, in the future it should be considered a "strong" relative contradindication to adding the combined oral contraceptive.

Safer pills

This meeting has attempted to identify these safer pills. I will not try to define the "best buy." However, it appears from recent research that the safer pills are "smaller": in almost all cases the estrogen dose should be 35 μg or less, and the minimum *acceptable* amount of selected progestogen should also be used. It also seems that the so-called "third-generation" progestogens in the doses available produce less potentially adverse changes in lipids, while not apparently causing more effects on hemostasis than available norethindrone or levonorgestrel varieties with the same estrogen dose. They also have a relatively low rate of breakthrough bleeding and other problems with the pill cycle. This is significant in regard to the word "acceptable."

Most would accept the dictum of Professor Victor Wynn: "If we can measure any substance in a pill-user, we would like it to be normal, or as near normal as possible." The most significant changes in circulatory disease are those affecting lipoproteins, the renin-angiotensin system, and coagulation. The liver is intimately involved in all these areas of metabolism. It appears that many of the pill's problems relate to its being a pill: far less impact is given to the liver if the same hormones are given by nonoral routes. However, for now we do not have these contraceptive alternatives in most countries.

Individual variation

Many researchers have shown the wide variation in both estrogen and progestogen pharmacokinetics that exists between individuals, which is associated with more than a 10-fold variability in blood levels.[7] There is similar variation in end organs. Far too little notice is taken in routine prescribing. It is futile to expect one dose level of a given estrogen-progestogen to suit all women. Ahluwalia et al.[8] showed a statistically significantly higher level of ethinyl estradiol in hypertensive pilltakers than in nonhypertensive women taking the same pills. In a major study at the Margaret Pyke Centre, we are attempting to confirm this and also to correlate a wide range of metabolic changes in blood levels of exogenous hormones. Many women could receive long-term higher doses than needed for satisfactory contraception and cycle control, consequently with greater risk of metabolic abnormalities and minor or major side

Table III. When to report if you have side effects[9]

Minor side effects should be mentioned at your next appointment
See the doctor at once if you have any of these:
- Painful swelling in the leg
- Severe pain in the chest or stomach
- Breathlessness or coughing with blood
- A bad fainting attack or collapse
- Unusual headaches, difficulty with speech/sight
- Numbness or weakness of a limb

effects, and only because no attempt was made to try a lower dose. The question is, how do we avoid giving the woman who tends to have the highest blood levels a stronger formulation than she really requires?

Breakthrough bleeding is an annoying symptom. When it occurs, it may be caused by low blood levels (witness the effect of an interacting drug such as rifampicin). However, even if lack of endometrial stability results from features of that end organ, it is still logical not to prescribe any more hormone than the minimum to give a good cycle. I have argued in more detail elsewhere that one should attempt to give each pilltaker the lowest dose of a selected estrogen-progestogen that the uterus allows,[1,2] with bleeding used as a "threshold bioassay." Manufacturers would help in this endeavor if they would provide different dose levels for the newer progestogens, such as those that already exist for norethindrone and levonorgestrel pills (i.e., a "ladder").[2]

Monitoring

After patients with absolute contraindications are excluded, those with risk factors identified, and a pill chosen that has the least biologic impact and is just above the threshold for cycle control, what should be done about monitoring?

In some patients in whom there are medical indications (e.g., treatment of endometriosis, to avoid hysterectomy with its associated risk, or when a disease is present that may deteriorate markedly in pregnancy), greater risk may be tolerated. Such women, along with those who have a solitary risk factor (Table I) interpreted as no more than a relative contraindication, still require careful monitoring for the development of any new risk factor. The rest need less supervision: the most essential factor is regular blood pressure checks, combined with ready access to the prescribing clinician. All pilltakers should be informed of those symptoms that should lead them to take urgent advice (Table III).[9]

Blood pressure

I believe that this is the single most important test for the ongoing safety of the pill. Insurance Company studies have shown for populations that increased blood pressure adversely affects life expectancy through cardiovascular disease, with no apparent threshold.[10] Prudence dictates that although its mechanism may differ, combined oral contraceptive–related hypertension is taken to have similar importance. Prescribers have often remarked how helpful it would be if there were some office test of safety, some special reagent that could be added to a body fluid such as urine, which would turn it "red" if the woman should discontinue taking the pill but "green" if she could safely continue to take it. I maintain that the development of combined oral contraceptive–related hypertension can be used in this way. If, for example, a 33-year-old smoker is found to have a blood pressure of 140/90 on repeated testing, this means that she should now use another birth control method (and not wait until the age limit of 35 years when all smokers should discontinue use of the pill). It is a "pink" test.

In conclusion, no one should be under any pressure to use oral contraception. The aim of good counseling is to provide sufficient information and advice so the woman fully exercises her right to consent to treatment, considers the alternatives, and assumes acceptable risks in life generally. I feel that it is essential to back up counseling with appropriate literature: leaflets, such as those already mentioned,[9] or a practical "handbook for the owner-driver"[11] for those patients seeking additional information.

FEMSTAT PREFILL

(butoconazole nitrate) VAGINAL CREAM 2%

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

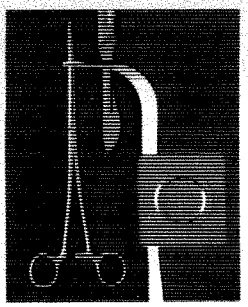
CEFOTAN® IM/IV



(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli.*
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.
NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.
INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.
DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.
CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

$$\text{Females:} \quad 0.9 \times \text{value for males}$$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

Effect of maternal-fetal movement on concentration of cells obtained at genetic amniocentesis 490
Stephen J. Carlan, MD, Peter Papenhausen, PhD, William F. O'Brien, MD, Marcello Pietrantoni, MD, Ronald A. Chez, MD, and Pamela Stephens, RN
Tampa, Florida

Maternal-fetal movement immediately before second-trimester genetic amniocentesis was not associated with a change in the cell concentration of the amniotic fluid sample.

Assessment of cerebral hemodynamics in pregnant women by internal carotid artery pulsed Doppler velocimetry 494
Tomoaki Ikeda, MD, and Norimasa Mori, MD
Miyazaki, Japan

Cerebral circulation in nonpregnant women and women with uncomplicated pregnancies was assessed by internal carotid artery Doppler velocimetry.

Changes in active and latent collagenase in human placenta around the time of parturition 499
Mohammad R. Rajabi, MD, David D. Dean, PhD, and J. Frederick Woessner, Jr., PhD
Miami, Florida

Human placenta at term contains collagenase and tissue inhibitor of metalloproteinase; collagenase levels increase significantly at parturition.

Preeclampsia in diabetic pregnancies 505
Peter R. Garner, MD, Mary E. D'Alton, MD, Denis K. Dudley, MD, Pierre Huard, MD, and Michael Hardie, MD
Ottawa, Ontario, Canada

A controlled clinical trial that compares the frequency of preeclampsia in diabetic pregnancies with the nondiabetic population and evaluates predisposing factors is presented.

Diabetic ketoacidosis and insulin resistance with subcutaneous terbutaline infusion: A case report 509
Joseph M. Tibaldi, MD, Daniel L. Lorber, MD, and Alan Nerenberg, MD
Flushing, New York

Diabetic ketoacidosis and transient severe insulin resistance developed in a pregnant woman with diabetes who was treated with subcutaneous terbutaline infusion tocolysis.

A follow-up study of methods of contraception, sexual activity, and rates of trichomoniasis, candidiasis, and bacterial vaginosis 510
Fabio Barbone, MD, DrPH, Harland Austin, DSc, William C. Louv, PhD, and W. James Alexander, MD
Birmingham, Alabama

A clinical trial demonstrated that spermicide slightly reduces the incidence rate of trichomoniasis and bacterial vaginosis and that oral contraceptive use strongly protects against trichomoniasis.

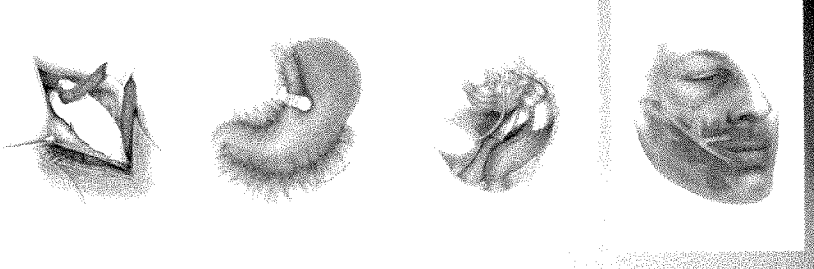
GORE-TEX® SOFT TISSUE PATCH



In reconstructive surgery, a patient's own tissue is not always adequate. However, today surgeons do have alternatives. When a biomaterial is indicated, the GORE-TEX Soft Tissue Patch is the natural choice.

This remarkable sheet of GORE-TEX (expanded polytetrafluoroethylene) is engineered to provide improved performance in a wide range of applications. Since its introduction in 1982, the GORE-TEX Soft Tissue Patch has been used in more than 50,000 clinical cases worldwide.

The GORE-TEX Soft Tissue Patch combines high, balanced strength with softness and conformability. It is easy to shape and contour without fraying. Its microporous structure allows natural tissue ingrowth leading to potential treatability in the presence of infection. Next to delicate internal organs, the GORE-TEX Soft Tissue Patch has shown a significant reduction in adhesion formation and tissue erosion.

The exceptional versatility of the GORE-TEX Soft Tissue Patch makes it the natural choice in a wide range of applications.

- Abdominal Wall Reconstruction
- Hernia Repair
- Thoracic Wall Reconstruction
- Diaphragm Reconstruction
- Rectal and Vaginal Suspension
- Urethral Suspension
- Gastric Banding
- Facial Augmentation and Sling Procedures
- Related Pediatric Reconstructions

☐ Please send further information on the GORE-TEX Soft Tissue Patch.
☐ Please arrange for a free clinical sample.
☐ Please have your sales representative call for an appointment.

Bacterial vaginosis: Diagnostic and pathogenetic findings during topical clindamycin therapy 515
Charles H. Livengood III, MD, Jessica L. Thomason, MD, and Gale B. Hill, PhD
Durham, North Carolina, and Milwaukee, Wisconsin

Insights into the symptoms, findings, diagnosis, and pathogenesis of bacterial vaginosis are provided by serial observations before and after therapy.

The relationship of cocaine use to syphilis and human immunodeficiency virus infections among inner city parturient women 521
Howard L. Minkoff, MD, Sandra McCalla, MD, Isaac Delke, MD, Roy Stevens, MD, Martin Salwen, MD, and Joseph Feldman, DrPH
Brooklyn and Albany, New York

A blinded urine and serum survey among parturients at an inner city hospital revealed an association between cocaine metabolites in urine and serologic evidence of syphilis and human immunodeficiency virus.

Rupture of unscarred uterus in primigravid woman in association with cocaine abuse 526
Whitney Gonsoulin, MD, David Borge, MD, and Kenneth J. Moise, Jr., MD
Houston, Texas

Cocaine abuse may be cause uterine rupture in patients predisposed to this because of placental abnormalities.

Prognosis for twins with birth weight <1500 gm: The impact of cesarean section in relation to fetal presentation 528
Håkan Rydhström, MD
Lund, Sweden

A study of 862 twins <1500 gm, born in Sweden during an 11-year period, failed to show significantly reduced mortality and morbidity after abdominal birth.

Recurrent acute fatty liver of pregnancy 534
John R. Barton, MD, Baha M. Sibai, MD, William C. Mabie, MD, and Douglas R. Shanklin, MD
Memphis, Tennessee

Electron microscopic examination of a liver biopsy specimen was used to confirm the first reported case of recurrent acute fatty liver of pregnancy.

Postpartum coronary artery dissection followed by heart transplantation 538
Piero Curiel, MD, Giansenio Spinelli, MD, Antonio Petrella, MD, Alessandro Gori, MD, Renata De Maria, MD, Edgardo Bonacina, MD, and Edoardo Gronda, MD
Prato and Milan, Italy

A rare case of postpartum coronary artery dissection was successfully treated by heart transplantation.

Induction of labor with mifepristone (RU 486) in intrauterine fetal death 540
D. Cabrol, MD, C. Dubois, MD, H. Cronje, MD, J. M. Gonnet, MD, M. Guillot, MD, B. Maria, MD, J. Moodley, MD, J. F. Oury, MD, J. M. Thoulon, MD, A. Treisser, MD, D. Ulmann, MD, S. Correl, MS, and A. Ulmann, MD
Paris, Romainville, Bordeaux, Pessac, Villeneuve St. Georges, Pontoise, Lyon, Strasbourg, and Cherbourg, France, and Bloemfontein and Durban, South Africa

The efficacy of mifepristone in the medical management of intrauterine fetal death in utero was 63% compared with 17.4% in the placebo-controlled group and the tolerance was satisfactory.

Mifepristone (RU 486) failure in an ovarian heterotopic pregnancy 543
Jay H. Levin, MD, Maria Lacarra, RN, Gerrit d'Ablaing, MD, David A. Grimes, MD, and Michael Vermesh, MD
Los Angeles, California

Heterotopic ovarian pregnancy may persist after treatment with the antiprogesterone mifepristone (RU 486) to induce abortion of a normal intrauterine pregnancy.

The impact of a quality assurance process on the frequency and confirmation rate of hysterectomy 545
Joseph C. Gambone, DO, Robert C. Reiter, MD, Joel B. Lench, MD, and J. George Moore, MD
Los Angeles and San Diego, California, and Iowa City, Iowa

The use of a standardized list of indications with criteria to be satisfied preoperatively reduced the frequency and improved the confirmation rate of hysterectomy.

Retropubic long-needle suspension procedures for stress urinary incontinence 551
R. Edward Varner, MD
Birmingham, Alabama

The benefits and negative aspects of the retropubic long-needle suspension procedures are briefly reviewed, and experience with new modifications is reported.

Ductus arteriosus flow velocity modulation by fetal breathing movements as a measure of fetal lung development 558
Jim van Eyck, PhD, Karin van der Mooren, MD, and Juriy W. Wladimiroff, PhD
Rotterdam, The Netherlands

Ductus arteriosus flow velocity in the human fetus is modulated by fetal breathing movements and appears to be indicative of fetal lung development.

Prenatal diagnosis of a chest wall mass with ultrasonography and Doppler velocimetry 567
Leon G. Smith, Jr., MD, Robert J. Carpenter, Jr., MD, Whitney Gonsoulin, MD, Giancarlo Mari, MD, Alexander A. Reiter, MD, Frank Greenberg, MD, and Carolyn Powell, RN, BSN
Houston, Texas

A fetus was diagnosed with a chest wall hemangioma at 30 weeks' gestation; radiographic findings and obstetric management are discussed.

Relationship of fetal biophysical profile and blood gas values at cordocentesis in severely growth-retarded fetuses 569
Lucie S. M. Ribbert, MD, Rosalinde J. M. Snijders, MSc, K. H. Nicolaides, MD, and G. H. A. Visser, MD
London, England, and Groningen, The Netherlands

In 14 severely growth-retarded fetuses there was a significant inverse association between the biophysical profile score and blood pH in samples obtained by cordocentesis.

Successful treatment of postpartum shock caused by amniotic fluid embolism with cardiopulmonary bypass and pulmonary artery thromboembolectomy 572
Rick A. Esposito, MD, Eugene A. Grossi, MD, Gene Coppa, MD, Gary Giangola, MD, Donald P. Ferri, MD, Elaine M. Angelides, MD, and Peter Andriakos, MD
New York, New York, and Monmouth, New Jersey

We report the successful treatment of a patient with amniotic fluid embolism using cardiopulmonary bypass and open pulmonary artery thrombectomy.

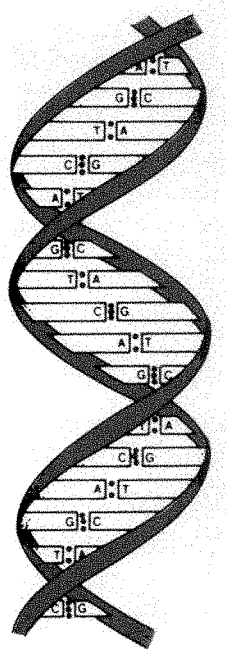
Antiphospholipid antibodies and recurrent pregnancy loss: Correlation between the activated partial thromboplastin time and antibodies against phosphatidylserine and cardiolipin 575
Neal S. Rote, PhD, Dorene Dostal-Johnson, MS, and D. Ware Branch, MD
Scarborough and Portland, Maine, and Salt Lake City, Utah

Although combined use of the activated partial thromboplastin time and an enzyme-linked immunosorbent assay for anticardiolipin antibody is adequate for detecting the majority of patients with antiphospholipid antibody–associated recurrent pregnancy loss, the addition of an assay for antiphosphatidylserine antibody detects patients who would otherwise remain undiagnosed and measures an antibody that may be more relevant to the pathophysiology of the antiphospholipid antibody syndrome.

Effect of mitral valve prosthetic surgery on the outcome of a growth-retarded fetus 584
Luis A. Izquierdo, MD, Ori Kushnir, MD, Karen Knieriem, MD, Jorge A. Wernley, MD, and Luis B. Curet, MD
Albuquerque, New Mexico

During mitral valve prosthetic surgery at 29 weeks' gestation, the intrauterine growth-retarded fetus died.

Laparoscopic diagnosis and treatment of interstitial ectopic pregnancy: A case report 587
Resad Pasic, MD, and Walter M. Wolfe, MD
Louisville, Kentucky



The laparoscope is used to diagnose and treat an interstitial pregnancy.

A vesicovaginal fistula and intravesical foreign body 589
Irwin Goldstein, MD, Gilbert J. Wise, MD, and M. Leon Tancer, MD
Brooklyn, New York

Patient neglect resulted in erosion of the anterior vaginal and bladder walls by a Gelhorn pessary found subsequently entirely within the bladder.

Vivigen Introduces Cystic Fibrosis Testing

- 1 in 25 Caucasians is a carrier of Cystic Fibrosis
- Direct DNA testing can now identify 70% of CF carriers
- For families at risk (those with a previous history of CF), indirect linkage or haplotype analysis can be performed

Physicians nationwide rely on Vivigen for thorough and accurate genetic testing, from chromosome analysis to biochemical and molecular genetics.

For more information about Vivigen's Cystic Fibrosis testing program, call 1-800-VIVIGEN or (505) 438-1111.

Malignant leiomyomatosis peritonealis disseminata 591
George J. M. Akkersdijk, MD, Peter K. Flu, MD, PhD, Raymond W. M. Giard, MD, PhD, Mattheus van Lent, MD, PhD, and Henk C. S. Wallenburg, MD, PhD
Rotterdam, The Netherlands

A case of malignant leiomyomatosis peritonealis disseminata is reported.

An abdominal pregnancy 10 years after treatment for pelvic tuberculosis 594
Tekin Durukan, MD, Bülent Urman, MD, Hakan Yarali, MD, Ünser Arikan, MD, and Ömer Beykal, MD
Ankara, Turkey

Infertility may rarely be restored after therapy for pelvic tuberculosis, but ectopic pregnancies are common; a case of abdominal pregnancy after such therapy is reported.

Papillary cystadenoma of the broad ligament in von Hippel-Lindau disease 596
William T. Korn, MD, Stefan C. Schatzki, MD, Anthony J. DiSciullo, MD, and Robert E. Scully, MD
Cambridge and Boston, Massachusetts

Papillary cystadenoma of wolffian duct origin is a rare tumor of the broad ligament that may be pathognomonic of von Hippel-Lindau disease.

Anencephalics as organ donors 599
F. Andre Van Assche, MD, PhD
Leuven, Belgium

That anencephalics can show pain reactions and have endocrine disorders can cause problems when organs are used for transplantation.

BASIC SCIENCE SECTION

Study of internal structure of the human fetus in utero by echo-planar magnetic resonance imaging 601
Ian R. Johnson, BSc, MB, BS, DM, Michael K. Stehling, DrMed, Andrew M. Blamire, BSc, Ronald J. Coxon, BSc, PhD, Alistair M. Howseman, BSc, Barry Chapman, BSc, PhD, Roger J. Ordidge, BSc, PhD, Peter Mansfield, BSc, PhD, Edwin M. Symonds, MD, Brian S. Worthington, BSc, MB, BS, DMRD, and Rex E. Coupland, MD, PhD, DSc
Nottingham, England

Our home-built imager with the ultra-fast echo-planar magnetic resonance imaging technique has produced the first echo-planar imaging snapshots of human fetuses in utero that were used for internal stucture studies.

Hyperkalemia after irradiation of packed red blood cells: Possible effects with intravascular fetal transfusion 607
James A. Thorp, MD, Fred V. Plapp, MD, PhD, Gary R. Cohen, MD, John D. Yeast, MD, Richard T. O'Kell, MD, and Stephanie Stephenson, RN
Kansas City, Missouri

Dangerously high levels of potassium may occur in packed red blood cell preparations as a result of many factors and may pose a risk to the fetus undergoing intravascular transfusion.

Contents

Lymphocyte proliferative response to fertilization antigen in patients with antisperm antibodies 610

Rajesh K. Naz, PhD, Anu Chaudhry, MD, and Steven S. Witkin, PhD

Bronx and New York, New York

Lymphocytes from infertile patients with antisperm antibodies are sensitized to the sperm antigen fertilization antigen and not to germ cell antigen.

Effects on bone of surgical menopause and estrogen therapy with or without progesterone replacement in cynomolgus monkeys 614

Manuel J. Jayo, DVM, PhD, David S. Weaver, PhD, Michael R. Adams, DVM, and Samuel E. Rankin, BA

Winston-Salem, North Carolina

Estrogen replacement therapy, with or without cyclic progesterone, protected against oophorectomy-induced (surgically postmenopausal) bone mass loss in cynomolgus macaques.

Embryopathic effects of short-term exposure to hypoglycemia in mouse embryos in vitro 619

Ida W. Smoak, DVM, and Thomas W. Sadler, PhD

Chapel Hill, North Carolina

Short periods of hypoglycemia produce dysmorphogenesis and growth inhibition in a dose-dependent and stage-dependent manner in postimplantation mouse embryos in vitro.

Ovarian granulosa cell tumorigenesis in SWR-derived F1 hybrid mice: Preneoplastic follicular abnormality and malignant disease progression 625

Barbara J. Tennent, PhD, Kathryn L. Shultz, BS, John P. Sundberg, DVM, PhD, and Wesley G. Beamer, PhD

Bar Harbor, Maine

Abnormal granulosa and theca cell proliferation in certain hemorrhagic follicles during pubertal maturation progresses to malignant ovarian tumors with high frequency in hybrid mice.

Differential diagnosis between complete mole and hydropic abortus by deoxyribonucleic acid fingerprints 634

Toshikatsu Nobunaga, MD, Chihiro Azuma, MD, DMSci, Tadashi Kimura, MD, Yoshihiro Tokugawa, MD, Masahiko Takemura, MD, Shoji Kamiura, MD, Fumitaka Saji, MD, DMSci, and Osamu Tanizawa, MD, DMSci

Osaka, Japan

Differential diagnosis between complete mole and hydropic abortus can be obtained by comparisons of deoxyribonucleic acid polymorphisms detected by the minisatellite deoxyribonucleic acid probe 33.15.

Gestational changes in mechanical properties of skinned muscle tissues of human myometrium 638

Hidetaka Izumi, MD, Jirou Ichihara, MD, Yoshio Uchiumi, MD, and Koichi Shirakawa, MD

Fukuoka, Japan

Both the contractile force and the sensitivity of the contractile proteins to Ca^{2+} in human myometrium increased during gestation.

Contents continued from page 15A

Alteration of 24-hour rhythms in myometrial activity in the chronically catheterized pregnant rhesus monkey after a 6-hour shift in the light-dark cycle 648
Jorge P. Figueroa, MD, PhD, M. Barbera O. M. Honnebier, MD, Susan Jenkins, and Peter W. Nathanielsz, MD, PhD
Ithaca, New York

A 6-hour phase shift in photoperiod shifted the initiation of nocturnal uterine activity in rhesus monkeys by approximately the same extent.

Nifedipine enhances the cardiac toxicity of magnesium sulfate in the isolated perfused Sprague-Dawley rat heart 655
John M. Thorp, Jr., MD, F. J. Spielman, MD, Fidel A. Valea, MD, F. G. Payne, MD, R. A. Mueller, MD, and Robert C. Cefalo, MD
Chapel Hill, North Carolina

In the isolated perfused rat heart (Sprague-Dawley rats), nifedipine enhances the depressive effects of magnesium sulfate on cardiac function.

Effect of intravaginal application of prostaglandin E_2 gel on the mechanical properties of the ovine cervix uteri at term 657
James R. Owiny, PhD, and Reginald J. Fitzpatrick, PhD
Liverpool, England

In sheep at term, intravaginal prostaglandin E_2 produced a fourfold increase in cervical tissue extensibility without eliciting uterine contractions or fall in progesterone.

Effects of clonidine on breathing movements and electrocortical activity in the fetal lamb 661
Owen S. Bamford, PhD, Robert L. Hawkins, BS, and Carlos E. Blanco, MD
Baltimore, Maryland

Central infusion of clonidine inhibits breathing and disrupts sleep state cycling in fetal lambs.

Dose response of thyrotropin-releasing hormone on pulmonary maturation in corticosteroid-treated preterm rabbits 669
Bannie L. Tabor, MD, Machiko Ikegami, MD, PhD, Alan H. Jobe, MD, PhD, Takako Yamada, MD, and Sidarto Bambang Oetomo, MD, PhD
Torrance, California

Single or multiple doses of thyrotropin-releasing hormone enhance pulmonary maturation when given in combination with betamethasone in preterm rabbits.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318 USA; phone (314) 872-8370, ext. 7394. In the U.S., call toll-free: 1-800-325-4177, ext. 7394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

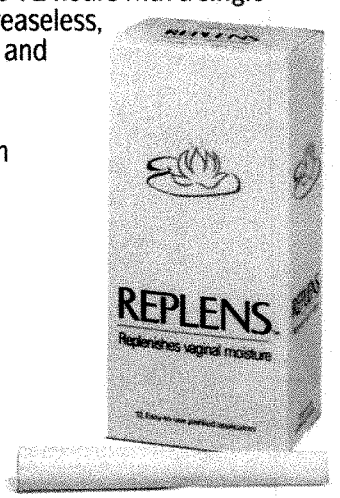
Moisture that lasts and lasts

The only proven vaginal moisturizer

Bioadhesive technology clinically proven to end vaginal dryness

Statistically significant results from a multicenter clinical trial have shown that REPLENS increases moisture and improves epithelial integrity.* Through unique bioadhesive technology, REPLENS provides ongoing hydration of underlying vaginal tissue to end discomfort and painful intercourse.



Nonhormonal relief for more than 25 million women

Although most prevalent during menopause, vaginal dryness can occur during many stages of a woman's life. All these patients will appreciate your recommendation of REPLENS. REPLENS is a very natural way to bring back a feeling of youth and confidence many women thought they had lost forever.

Three times a week for full-time comfort

REPLENS relieves vaginal dryness, discomfort, and painful intercourse for up to 72 hours with a single application. REPLENS is greaseless, odorless, and nonirritating and packaged in disposable applicators for ease of use.

Call toll-free for information 1-800-749-1919.

TRI-NORINYL

Uniquely phased for all phases of a woman's reproductive life

ORAL CONTRACEPTIVE AGENTS: BRIEF SUMMARY

DESCRIPTION

TRI-NORINYL 21-DAY Tablets provide an oral contraceptive regimen of 7 blue tablets followed by 9 yellow-green tablets and 5 more blue tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg and each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg.

TRI-NORINYL 28-DAY Tablets provide a continuous oral contraceptive regimen of 7 blue tablets, 9 yellow-green tablets, 5 more blue tablets, and then 7 orange tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg, each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg, and each orange tablet contains inert ingredients.

INDICATIONS AND USAGE

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use these products as a method of contraception.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions: Thrombophlebitis or thromboembolic disorders • A past history of deep vein thrombophlebitis or thromboembolic disorders • Cerebral vascular or coronary artery disease • Known or suspected carcinoma of the breast • Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia • Undiagnosed abnormal genital bleeding • Cholestatic jaundice of pregnancy or jaundice with prior pill use • Hepatic adenomas, carcinomas or benign liver tumors • Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long-term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users, cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS,** section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral contraceptive users is based on data gathered in the 1970's—but not reported in the U.S. until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral contraceptive use to women who do not have the various risk factors listed in this labeling.

Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular disease risks may be increased with oral contraceptive use after age 40 in healthy non-smoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception.

Therefore, the Committee recommended that the benefits of oral contraceptive use by healthy non-smoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (> 8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T4 concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING.**

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section): Thrombophlebitis • Arterial thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemorrhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenomas, carcinomas or benign liver tumors

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis • Retinal thrombosis

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spotting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminution in lactation when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepening) • Intolerance to contact lenses

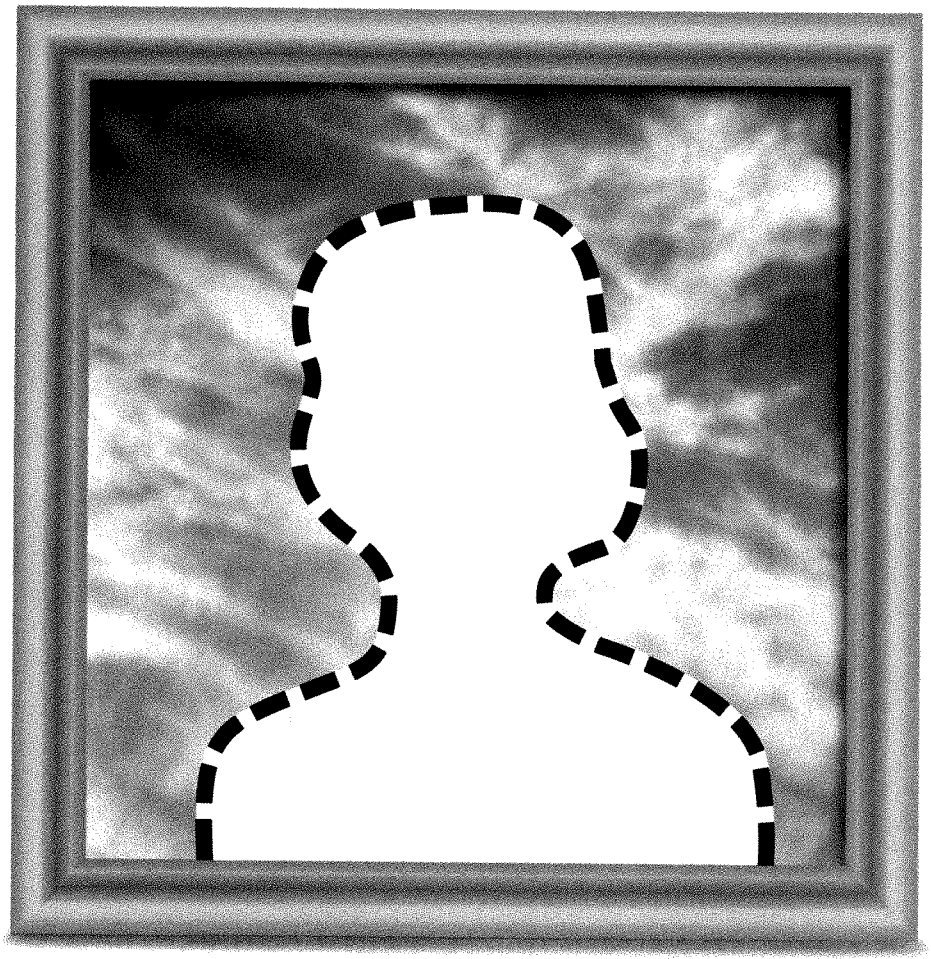
The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome • Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness • Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.



Effects on menses: • Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea

Effects related to inhibition of ovulation: • Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use: • Decreased incidence of fibroadenomas and fibrocystic disease of the breast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

Picture your OC patients here.

Your younger patients just starting contraception, because low impact norethindrone lowers the risk of acne and bloating.

Your career-oriented patients delaying childbearing, because reduced progestin helps avoid late cycle side effects, such as weight gain, headache, and depression.

Your older, nonsmoking patients restarting contraception, because Tri-Norinyl is the only multiphasic OC to lower progestin in the late cycle to minimize overall hormonal impact.

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL

Uniquely phased for all phases of a woman's reproductive life

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see adjacent page for brief summary of prescribing information. © 1990 Syntex Laboratories, Inc. 814-G2-116-89

DIAGNOSTIC AND OPERATIVE HYSTEROSCOPY:

A TEXT AND ATLAS

By:

Michael S. Baggish, M.D., F.A.C.O.G., F.A.C.S.
Professor and Chairman SUNY, Health Sciences Center, Syracuse; Department of Obstetrics and Gynecology; Chief, Obstetrics and Gynecology, Crouse-Irving Memorial Hospital, Syracuse NY

Jacques Barbot, M.D.
Ancien Interne des Hopitaux de Paris,
Ancien Chef de Clinique
Assistant de Hopitaux Chivurgien-Gynecoloque-Obstetricien
Paris, France

Rafael F. Valle, M.D.
Associate Professor, Department of Obstetrics and Gynecology, Northwestern University Medical School, Chicago, Illinois

With Contributors

This comprehensive textbook examines hysteroscopy and the uterus in general. It represents the most complete treatment of the subject to date and includes 300 color photographs, over 100 drawings, and over 100 black & white photographs.

Chapters include:

- Anatomy of the Uterus
- Embryology of the Uterus
- Physiology and Pathology of the Uterus
- Physics of Endoscopy
- How to Learn Hysteroscopy
- Contact Hysteroscopy
- Operative Hysteroscopy I
- Endoscopy During Pregnancy
- Care and Maintenance of Hysteroscopes

"This volume fillls an important void in the field of hysteroscopy. It is not only a thorough presentation of current techniques and a clear appraisal of the instrumentation available, but it is also a review of the embryology, anatomy, physiology, and pathology of the uterus, with particular emphasis on those items that relate directly to hysteroscopy."

1988 approx. 304 pp./706 illus. ***$160.00*** ***– From the Preface***

Prepaid orders are shipped postage free; add $3.50 per order to cover handling. IL, MA, TN residents will be billed appropriate sales tax. Prices quoted in U.S. dollars. Canadian orders payable in U.S. funds. All prices subject to change without notice.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the

Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number are allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Abstracts are not acceptable as numbered references.

Illustrations and tables. Illustrations and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice.

A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3×4 inch (minimum) to 5×7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in

sequence after the references. Titles should be included in the legend, *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words [excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"]. The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy photographic prints are submitted, properly numbered and labeled on the back of each print.
—Three sets of computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title
—Author(s) name(s) and highest academic degree(s)
—City(ies), state(s), and country other than U.S. in which the study was conducted are given
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated
—Acknowledgment of financial support is cited
—Name, address, and business and home telephone numbers of author to whom requests for reprints are to be sent
—Reprints will not be available. This has been stated on the title page
—Since the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, and business and home telephone numbers have been added
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a caption and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in sequence in the text.

Figures

—Are numbered in Arabic numerals and are cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Abstracts, personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted and the signed approval is enclosed.

CLINICAL SECTION

Clinical Opinion

Prenatal diagnosis of congenital cytomegalovirus infection: Two decades later

Charles Grose, MD, and Carl P. Weiner, MD

Iowa City, Iowa

Cytomegalovirus is the most common cause of congenital infection in the United States, yet there has been little progress in the prenatal diagnosis of this intrauterine infection. We present evidence that viral culture of amniotic fluid may be a useful adjunct procedure, when performed as part of the antenatal evaluation of suspected fetal cytomegalovirus infection. (AM J OBSTET GYNECOL 1990;163:447-50.)

Key words: Cytomegalovirus, prenatal diagnosis, congenital infection

Cytomegalovirus (CMV) is the most common cause of congenital infection, affecting 30,000 to 40,000 live-born infants annually in the United States.[1,2] However, prenatal diagnosis of fetal CMV infection has received little attention over the last 20 years and was not mentioned in a recent editorial strongly urging renewed efforts to eliminate the problem.[3] In this Clinical Opinion, we briefly survey the epidemiologic characteristics of congenital CMV infection. Then we review published methods of prenatal diagnosis and provide evidence for our opinion that viral cultures of amniotic fluid may be a useful procedure. Finally, we suggest that antenatal diagnosis can play an important role in suggested programs that seek to prevent congenital infection and to treat those cases that do occur.

CMV is one of the human herpesviruses, which also include herpes simplex virus types 1 and 2, varicella-zoster virus, Epstein-Barr virus, and human herpesvirus type 6. Pregnant women usually acquire the initial CMV infection by exposure to body excretions (saliva, urine) of young children or by intimate sexual contact.[1-3] Women at greatest risk are those <25 years old and those with young children in the home.[4] Women who contract the infection often have a subclinical course; a small number manifest a mononucleosis-like syndrome 4 to 8 weeks later, which is characterized by fever, splenomegaly, thrombocytopenia, and atypical lymphocytosis. If the virus first enters via the nasopharyngeal or oropharyngeal route, it next spreads to the salivary glands, where it replicates before gaining access to the maternal circulation. During the viremic phase, the virus may localize in the fetus of a pregnant woman.

The risk of fetal infection is likely the same throughout pregnancy, but its destructive potential is greatest after primary maternal infection in the first half of gestation.[1,2] It is estimated that CMV will be transmitted to 50% of fetuses after primary infection and that 10% of these infants will be clinically affected.[1,2] The number of severely damaged infants has been estimated between 1500 and 4000 per year.[1-3] Many congenitally infected infants will appear normal at delivery but manifest delayed neurologic sequelae. The mechanism of CMV transmission to the fetal tissues has not been thoroughly eludicated, but transmission may occur hematogenously when infected leukocytes traverse the placental barrier to reach the fetal circulation via the um-

Table I. Prenatal diagnosis of CMV infection by amniocentesis

Reference No.	*Year*	*Maternal symptoms and date*	*Prenatal ultrasonography*	*Date (wk) at amniocentesis*	*Fetal outcome*
5	1971	CMV mononucleosis at 8 wk	No	21	Abortion at 22 wk. Inclusion bodies in pancreas, lungs, liver, kidneys; no congenital anomalies
6	1981	CMV hepatitis at 12 wk	No	36	Term newborn. Undescended testis; right equinovarus; hypotonia
7	1982	None	IUGR	32	Term newborn. Severe congenital CMV syndrome (IUGR, microcephaly, hepatosplenomegaly, intracerebral calcifications, jaundice, thrombocytopenia)
8	1984	Flu syndrome at 10 wk	Polyhydramnios, fetal ascites	33	Premature newborn (33 wk). Ascites, microcephaly, hepatosplenomegaly, hypoplastic lungs, thrombocytopenia. Autopsy results: inclusion bodies in liver, kidneys, pancreas; cerebral ventriculomegaly
8	1984	None	IUGR and microcephaly	25	Abortion at 30 wks. No congenital anomalies
9	1986	None	Cerebral ventriculomegaly, posterior fossa cyst	36	Newborn (37 wk). Severe congenital CMV syndrome (hepatosplenomegaly, intracerebral calcifications, diffuse brain atrophy, dilated cisterna magna)
10	1988	None	Fetal ascites	28	Preterm newborn (36 wk). Petechiae, hepatomegaly, thrombocytopenia, and respiratory difficulty
11	1988	None	Polyhydramnios, fetal hydrops, cerebral ventriculomegaly	28	Term newborn. Microcephaly; agenesis of corpus callosum; hepatomegaly; borderline IUGR
12	1990	Fever, loose stools, uterine tenderness at 37 wk	IUGR, right hydronephrosis, oligohydramnios	37	Term newborn. Caudate nucleus cyst; right hydronephrosis; borderline IUGR
12	1990	None	Pericardial effusion	23	Term newborn. No stigmas of congenital CMV infection

IUGR, Intrauterine growth retardation.

bilical cord vessels. However, other routes may be equally accessible to viral transmission. For instance, the virus may infect placental tissues first and then amniotic cells. Consequently, infected amniotic cells would be ingested by the fetus, after which virus could replicate in the oropharynx and invade the fetal circulation to reach target organs. The tubular epithelium within the kidney appears to be a major site of viral replication. By either mechanism of infection, the fetus would excrete CMV via urine into the amniotic fluid. The amniotic fluid therefore would seem a logical choice of bodily fluid for determination of fetal CMV status.

The first report of CMV isolation from the amniotic fluid was published in this JOURNAL in 1971.[5] Nine additional case reports of antenatally diagnosed CMV infection after amniocentesis are summarized in Table I.[6-12] In contradistinction to the positive findings chronicled in Table I, Stagno et al.[13] briefly mentioned three anecdotal cases in which viral cultures of amniotic fluid were negative even though CMV was isolated from the infants postnatally. Unfortunately, no further prenatal history was given, thus making interpretation difficult. In view of the well-documented neonatal course of congenital CMV infection were viruria is a constant finding, it is difficult to accept the negative findings of Stagno et al.[13] as commonplace. Taken together, the data in Table I strongly suggest that viral culture of amniotic fluid should be obtained in pregnant women

in whom primary CMV infection is suspected or documented. Likewise, CMV cultures may be indicated when ultrasonography reveals fetal problems such as intrauterine growth retardation, hydrops or ascites, and central nervous system abnormalities. In the cases cited in Table I, eight had abnormal findings on ultrasonographic examination of the fetus. In the remaining two cases, ultrasonography was not performed.

In addition to amniocentesis, other techniques have been applied toward the detection of fetal CMV infection. In 1982, Lange et al.[14] reported on a 28-year-old woman at 25 weeks of gestation who was found to have a hydropic fetus by ultrasonography. Pure fetal blood was obtained by fetoscopy. Total immunoglobulin M content in the serum was modestly elevated at 11 mg/dl. Radioimmunoassay for CMV-specific immunoglobulin M showed a high titer in fetal serum, as well as in maternal serum obtained at 21 weeks' gestation. At birth, CMV was isolated from the urine. In 1988 Hogge et al.[15] performed cordocentesis at 36 weeks of gestation on a pregnant woman whose fetus had sonographic evidence of severe hydrocephalus and unilateral hydronephrosis. They detected CMV-specific immunoglobulin M at a titer of 1:256 in the fetal blood sample. Because of severe fetal anomalies, labor was induced after cephalocentesis. (No CMV culture results were mentioned in the report.) Although cordocentesis has supplanted fetoscopy for fetal blood sampling and may be a preferred alternative to amniocentesis since more information can be obtained about the hematologic status,[16-18] amniocentesis is a more widely available procedure. For the above reasons, viral culture of amniotic fluid may be at the minimum a useful adjunct when fetal CMV infection is suspected. At the present time there is no information about isolation of CMV from amniotic fluid before 21 weeks of gestation (see Table I).

Why attempt any antenatal diagnosis? There are several reasons. First, it will aid in the study of the natural history of congenital CMV infection; e.g., the latest case in Table I describes for the first time a transient fetal abnormality (a pericardial effusion likely the result of pericarditis) associated with fetal infection. Second, asymptomatic neonates may develop sequelae in later life. Forewarned with knowledge of a congenital infection, family and health care workers will be better equipped at early detection of these sequelae. Third, antenatal diagnosis may allow identification of parameters that discriminate between those fetuses that are infected but fail to develop the congenital syndrome and those with severe sequelae; e.g., will the latter group persistently excrete virus into the amniotic fluid since they usually exhibit prolonged viruria postnatally? The fourth reason for antenatal diagnosis is the potential application of fetal therapy. Because of recent advances in monoclonal antibody technology, CMV cultures can now be read in 1 to 3 days rather than 1 to 3 weeks.[19] Thus results of the amniotic fluid cultures are quickly available to both physician and patient. With advances in viral chemotherapy, antenatal diagnosis of fetal CMV infection may lead to treatment of the mother with an antiviral agent known to cross the placenta. Ganciclovir has shown efficacy in treatment of CMV-induced retinitis and is currently being administered to newborn infants who were congenitally infected with CMV.[2, 3] Pathologically, treatment of the affected neonate is likely too late. Much of the virally induced damage to the infant may already have occurred before delivery. If intrauterine treatment were safe and effective, it would encourage routine CMV serologic screening to identify women at risk (those who lack CMV antibody at onset of pregnancy).[3] Similar therapeutic interventions have already been initiated for the prenatal treatment of fetal toxoplasmosis in regions where the infection is endemic.[20]

In conclusion, we concur that congenital CMV infection is a major health problem which has received inadequate attention. Though its precise sensitivity is unknown, amniotic fluid culture for CMV diagnosis is a useful adjunct, as illustrated by the 10 cases in Table I. The procedure can easily be performed as part of the prenatal evaluation of suspected congenital CMV infection.

A chill wind blows: Webster, obstetrics, and the health of women

Wendy Chavkin, MD, MPH, and Allan Rosenfield, MD
New York, New York

The Supreme Court decision in *Webster v Reproductive Health Services* permits states to regulate abortion in fashions that may be medically unsound and may significantly restrict access. This decision challenges the contemporary practice of obstetrics and threatens to curtail access to needed services, particularly for poor women, who are at highest risk of pregnancy-associated medical complications and death. Governmental restrictions on abortion interfere with the obstetrician's basic goal of providing optimal care for the patient. Obstetricians dedicated to providing the best care to their patients should help to ensure that safe abortion be part of a spectrum of reproductive health care that is available to all American women. (AM J OBSTET GYNECOL 1990;163:450-2.)

Key words: Webster decision, abortion, maternal mortality, infant mortality, reproductive health

Justice Blackmun, in his dissenting opinion to the Supreme Court decision in the *Webster v Reproductive Health Services* case, wrote that: "I fear for the future.—For today—the women of this nation still retain the liberty to control their destinies. But the signs are evident and very ominous and a chill wind blows."[1] We concur with Justice Blackmun and fear that the chill wind blows most seriously for poor women, those most threatened by the Webster decision.

The decision effectively states that, short of prohibiting abortion within the first 24 weeks of gestation, a state may regulate performance of the procedure however it chooses, apparently even if that regulation is medically unsound and so encumbers the procedure as to significantly restrict access. The specific provisions that the State of Missouri has been permitted to enforce include prohibition on the use of public funds, facilities, and personnel for the performance of abortion, even if paid for by the patient, and inappropriate viability testing requirements.[2] In the latter case amniocentesis to measure the lecithin/sphingomyelin (L/S) ratio, for example, is not reliable as a measure of lung maturity until 30 gestational weeks or later. It is, in our opinion, medically contraindicated to recommend an invasive procedure, such as amniocentesis, when it is known that the results will not be informative or useful. Moreover, the court refused to rule on the preamble to Missouri's abortion law that declares that life begins at conception and defines conception as fertilization.

The very shape of contemporary obstetrics is challenged, and future developments constricted, if the state's "compelling interest" in fetal life is extended back to the moment of fertilization. Prenatal diagnosis, for example, would become of limited value with diagnostic capabilities far exceeding therapeutic possibilities. Implicit in offering α-fetoprotein screening, chorionic villus sampling, amniocentesis for karyotyping, and other probes for specific fetal abnormalities is the option of termination of pregnancy. Without such an option, there is little rationale for carrying out these testing procedures.

Future developments in reproductive medicine are likewise restricted. Why explore low α-fetoprotein values as a screen for Downs syndrome or pursue prenatal diagnostic probes for cystic fibrosis, muscular dystrophy, etc., if there is no possibility of subsequent action? Progesterone antagonists and in vitro fertilization are examples of developments in reproductive research whose mode of action may cause them to be similarly threatened by the definition of conception as occurring at the time of fertilization. Governmental enforcement of particular theologic beliefs about conception and embryonic and fetal status will have a negative impact on the future of scientific advancement in reproductive medicine.

Legal first-trimester abortion has been one of the most scrutinized surgical procedures and has been demonstrated to be one of the safest.[3] Procedure-associated complications decreased as operator skill and experience grew.[4] If performance of abortion is not regularly included in obstetrics and gynecology training programs, it is likely that as experience decreases, complications will again rise, particularly for second-trimester procedures. Instead of training obstetrics and gynecology residents to be competent at this surgical procedure, we may soon have to teach them once again to diagnose and treat sepsis and other complications of an unsafe abortion.

On every previous occasion in which the Supreme Court has addressed the abortion issue, the Court has clearly stipulated that maternal health be the physician's paramount consideration and that her health cannot be sacrificed on behalf of the fetus.[5, 6] Indeed the trimester approach was based in part on the fact that legal abortion during the first trimester was safer than continuing the pregnancy to term. Today, for both first- and second-trimester legal abortion procedures, the risk of maternal death is significantly lower than that associated with childbirth.

While risks associated with both legal abortion and childbirth declined in the 1970s, the abortion-related risks declined much more steeply. From 1970 to 1982 maternal mortality associated with delivery declined 30% while abortion-associated mortality declined 89% and is approaching zero.[7]

The women most at risk of pregnancy-associated death or serious medical complications are the very women most likely to be affected by the prohibition on the use of public resources for abortion. The State of Missouri (and potentially others) is thus forcing poor women to endure significant risks and forcing physicians to collude in this.

Interestingly, restricted access to legal abortion for poor, high-risk women is likely to increase infant mortality rates. Access to legal abortion has been associated with a decline in infant mortality, attributed to the prevention of unwanted and high-risk pregnancies. Multivariate analysis of the impact of various health and social services on race-specific neonatal mortality revealed that access to abortion was the single most important factor in the reduction in the black neonatal mortality rate. In addition, the decline in the black neonatal mortality rate varied with financial access to this service.[8]

The effect of each of the Missouri restrictions will be to delay abortion, particularly for those women for whom financial barriers are significant. While the risks of serious complications of legal abortion remain less than for childbirth, they do rise with increasing gestational age.[7] Thus, by imposing cost and delay on women seeking abortion, such governmental regulations impose health risks. Lack of access to medical care always has the worst impact on those most in need of the service because they are already at higher health risk.

In the past decade, obstetricians have been involved in initiatives to decrease infant mortality in the United States, as well as maternal mortality internationally, by providing high-risk women with reproductive health care. Restrictions on access to abortion undermine these efforts to improve maternal and infant health.

Indeed restrictions on abortion subvert the physician's fundamental goal: to provide optimal care to the patient. Obstetricians working in public facilities, for example, will find themselves impeded in providing the best care to their patients if they can neither counsel patients about the option or advisability of termination of pregnancy nor ensure access.

In a recent review Annas et al.[9] pointed out that governmentally imposed constraints on communication between doctor and patient constitute a grave threat to the practice of medicine. Such regulation undermines a critical component of the doctor-patient relationship: the ability to freely and confidentially discuss options, absent outside intrusion. Indeed the legal doctrine of informed consent requires physicians to

share information with patients. The authors conclude that physicians and patients have a united interest in defending the right of privacy that protects their joint decision-making from governmental interference.

Historians inform us that one hundred years ago physicians worked to criminalize abortion partly in an effort to protect the health of women from unregulated, incompetent abortionists and partly to bolster their own professional identity and moral prestige.[10] Today these same goals demand that obstetricians work vigorously to ensure that safe abortion is part of a spectrum of reproductive health care that is accessible to all women in the United States.

Chronic renal disease and pregnancy outcome

F. Gary Cunningham, MD, Susan M. Cox, MD, Timothy W. Harstad, MD, Ruble A. Mason, MT, and Jack A. Pritchard, MD
Dallas, Texas

During the 18-year period from 1971 through 1988, 37 women whose pregnancies were complicated by moderate or severe renal insufficiency were managed at Parkland Memorial Hospital. Common maternal complications included anemia, chronic hypertension, and preeclampsia. Perinatal complications included midpregnancy losses and low birth weight from preterm delivery, fetal growth retardation, or both. Despite the high incidence of maternal morbidity, 85% of pregnancies in the 26 women with moderate renal insufficiency resulted in a live-born infant; there was one stillbirth and no neonatal deaths. Of the 11 women with severe disease, seven were delivered of live-born infants after ≥26 weeks' gestation. Although six of these 37 women had worsening renal function during pregnancy, it seems unlikely that pregnancy per se caused this. More importantly, in four of these six women and in four others who had stable function throughout pregnancy, end-stage renal disease developed within a mean of 4 years after delivery. In 14 women blood volume was determined during pregnancy, and whereas those with moderate disease had normal volume expansion, women with severe disease had significantly attenuated expansion. Finally, serial creatinine clearances did not increase during pregnancy in half the women with moderate insufficiency and none with severe dysfunction. (Am J Obstet Gynecol 1990;163:453-9.)

Key words: Chronic renal insufficiency, pregnancy outcome

The effects of pregnancy on the natural course of chronic renal disease are not entirely clear. Whereas mildly impaired renal function usually does not worsen during pregnancy and generally is accompanied by uneventful pregnancy outcomes,[1] women with more seriously impaired renal function appear to do less well. For example, Hou and colleagues[2] described 23 women with moderate renal insufficiency, defined by a serum creatinine of ≥1.4 mg/dl, and approximately one third of these had worsening renal function during pregnancy. Other complications including hypertension and superimposed preeclampsia also were frequent. Although 92% of these women had live-born infants, 60% of these were delivered preterm, and the neonatal mortality rate was 10%. In this and most other studies of pregnant women, the degree of renal impairment was only mild. Pregnancy outcomes with more severe renal disease are less well defined but generally are assumed to be worse, and our purpose now is to describe our experiences with pregnancy complicated by moderate and severe renal insufficiency. In some of these women, blood volume was determined with erythrocytes labeled with chromium 51 and the magnitude of pregnancy-induced hypervolemia was correlated with the degree of renal insufficiency. Finally, whereas normal augmentation of pregnancy-induced glomerular filtration has been observed in women with mild renal disease, the response of those with more severe disease is unknown. We now report our observations in women with moderate or severe renal insufficiency.

Material and methods

Patients. During the 18-year period from 1971 through 1988, 37 women with chronic renal insufficiency were followed up prospectively during pregnancy by at least one senior investigator (F. G. C. or J. A. P.). Creatinine in serum and urine was measured by the Jaffe method, which has an accuracy at 2 mg/dl and 5 mg/dl of 2.05 ± 0.13 and 4.98 ± 0.2, respectively.[3] The criteria of Davison and Lindheimer[4] were used to categorize the intensity of renal impairment;

6	Chronic pyelonephritis	1.4	3.8	Acute pylonephritis	Preterm, 2500 gm	15 years; mild hypertension serum creatinine 1.5 mg/dl

moderate insufficiency was defined by a serum creatinine concentration of 1.4 to 2.5 mg/dl, whereas severe impairment was defined by concentrations >2.5 mg/dl.

Definitions. Chronic hypertension was diagnosed if the diastolic blood pressure exceeded 90 mm Hg before pregnancy or before 20 weeks' gestation. In women with chronic hypertension, superimposed preeclampsia was defined as an increase in blood pressure along with development of proteinuria or significantly increased existing proteinuria. Anemia was defined by a hematocrit <30%. Arbitrarily, we considered worsening renal function to be significant in women whose serum creatinine levels increased by 50% during pregnancy. First-trimester abortions were excluded from analysis. Previability was defined as spontaneous or induced delivery before 26 weeks' gestation. Other outcomes assessed included perinatal death, fetal growth retardation defined by birth weight <10th percentile for gestational age, and preterm delivery defined as before 37 completed weeks' gestation. Mean serum creatinine values for each woman were plotted as a function of birth weight and linear regression was used to analyze this relationship. The paired Student *t* test[5] was used to compare creatinine clearances determined from 24-hour urine collections obtained in late pregnancy with those performed when the women were not pregnant.

of another investigation, we used the patients' erythrocytes labeled with chromium 51 to determine red cell mass and apparent blood volume in 14 of these women. Blood volume determinations were performed as previously described.[9] Informed consent was obtained, although these studies were conducted at a time before the general implementation of severe restrictions on the use of small amounts of radioisotopes in studies during pregnancy.[6] About 20 to 25 μCi were used for each determination, and the total maternal body dose was calculated to be approximately 6×10^{-3} cGy.[7] In women in whom preeclampsia developed, blood volume determinations made before the disease was clinically apparent were used for analysis. In 10 women, the blood volume was determined again when they were nonpregnant, and in four women calculated nonpregnant values were used for comparative purposes. From prior observations in normal nonpregnant women[8, 9] we determined that the blood volume was predictable within 10% of the radiochromium method by the following formula:

$$\frac{[\text{Weight in pounds} \times 25] + [\text{Height in inches} \times 50]}{2}$$

In all 14 of these women, plasma was obtained along with timed urine collections at least once during late pregnancy for determination of creatinine clearance by standard methods. In most women, serial clearances were determined, and in 12, creatinine clearance was again determined at least 6 weeks post partum.

Results

Maternal outcomes in the 37 women with moderate and severe chronic renal insufficiency are summarized separately in Table I. In the 26 women with moderate disease, serum creatinine averaged 1.7 mg/dl (range, 1.4 to 2.5 mg/dl) and five (19%) subsequently had a ≥50% increase in creatinine concentration during pregnancy. Of these 26 women, anemia was identified in 19 (73%) and 16 (62%) had chronic hypertension that was further complicated by superimposed preeclampsia in 80% of those whose pregnancy progressed beyond 26 weeks. By contrast, preeclampsia developed in one third of the women without chronic hypertension.

Also shown in Table I are the outcomes in 11 women with severe renal insufficiency whose creatinine levels averaged 4.8 mg/dl (range, 2.6 to 9.4 mg/dl). Although only one of these women demonstrated a

significant increase in serum creatinine during pregnancy, two women were first seen at 18 and 20 weeks' gestation with end-stage renal failure and serum creatinine concentrations of 8.1 and 9.4 mg/dl, respectively. All women with severe disease had anemia, and chronic hypertension (80%) and preeclampsia (65%) also were frequent complications.

Further clinical details from the six women who were identified to have a ≥50% increase in serum creatinine concentration (mean 2.4 mg/dl; range, 1.9 to 3.0 mg/dl) are given in Table II. Five of these women were chronically hypertensive. These women were followed up for a mean of 5 years after delivery and four required dialysis 30 months on average after delivery. Long-term follow-up was available for only seven women whose renal function remained unchanged during pregnancy. They were followed up for a mean of 44 months and six had deterioration of renal function with four requiring dialysis by a mean interval of 39 months.

Fetal outcomes for these 37 pregnancies are summarized in Table III. Of the 26 women with moderate disease, there were two midtrimester losses before viability. Another 760 gm fetus died at 30 weeks; the mother had chronic hypertension and her serum creatinine level increased by >50% during pregnancy. There were no neonatal deaths in this group. In four of the 11 pregnancies complicated by severe disease, there was one midtrimester loss before viability. Two of these were induced abortions in women who required hemodialysis for end-stage renal disease, one pregnancy terminated spontaneously in a woman whose serum creatinine level was 5.7 mg/dl, and the fourth woman underwent abortion because of severe preeclampsia at 20 weeks' gestation. There were no perinatal deaths after 26 weeks' gestation in this group. As shown in Table III, compared with women with severe disease, those with moderate disease were more likely to be delivered of live births (88% versus 64%) and they had a lower incidence of fetal growth retardation (35% versus 43%) and preterm delivery (30% versus 86%).

Perinatal outcomes were analyzed separately for the 21 women with chronic hypertension. As shown in Table IV, fetal growth retardation and preterm delivery were identified more commonly in chronically hypertensive women with severe renal insufficiency. To determine whether birth weight was related to the degree of renal dysfunction, birth weights of the 29 live-born infants were plotted against maternal mean serum creatinine concentrations. As shown in Fig. 1, birth weight decreased significantly as creatinine concentration increased ($p < 0.001$).

The mean serum creatinine concentration of the 14 women who had blood volume determinations during pregnancy was 2.4 mg/dl and ranged from 1.4 to 5.5 mg/dl. Ten of these had moderate and four had severe disease. Nine women (64%) were known to have chronic hypertension before pregnancy, and superimposed preeclampsia developed in four of them. In the five women who were normotensive before pregnancy, preeclampsia developed in one. Mean blood volume determinations for these women are summarized in Table V, and are compared with volumes measured in normally pregnant women.[8, 9] As a group, pregnancy-induced hypervolemia developed in these women comparable to that of normal women. When the nine women with antecedent chronic hypertension were analyzed further, a normal volume expansion again was established.

To determine whether the degree of blood volume expansion correlated with the severity of renal impairment, the mean volumes for women with moderate and severe disease were compared. Whereas hypervolemia developed in the 10 women with moderate renal dysfunction similar to that of normally pregnant women, the four women with severe disease had significantly attenuated volume expansion. These latter four women had chronic hypertension and superimposed preeclampsia developed in two of them. As shown in Fig. 2, there was a significant inverse relationship between the incremental increase in blood volume plotted as a function of serum creatinine.

Blood volume measurements during pregnancy and remote from delivery in 10 women enabled us to quantify red cell mass expansion, which we found to be related inversely and significantly to serum creatinine. Erythrocyte mass expanded a mean of 26% in women with renal insufficiency, compared with 32% for normally pregnant women.[8, 9] Whereas this difference was not significant ($p = 0.13$), women with moderate renal insufficiency had significantly greater erythrocyte mass expansion compared with those with severe disease (26% versus 16%, $p = 0.04$). Because most of these women with renal disease already were anemic when nonpregnant (mean hematocrit, 31%), anemia was intensified during pregnancy because of disparately increased plasma volume compared with red cell mass. During late pregnancy their mean hematocrit was 27%, and in only three of the 14 was it ≥30%.

Creatinine clearance was determined in these same 14 women during pregnancy and again >6 weeks post partum. The late pregnancy mean clearance of 49 ml/min (range, 22 to 78 ml/min) was not significantly different from the nonpregnant mean of 52 ml/min (range, 16 to 77 ml/min). To determine whether changes in the glomerular filtration rate were related to blood volume expansion, we compared clearances that were determined in 12 of these women during pregnancy with clearances obtained again post partum. In eight women with moderate renal insufficiency, creatinine clearance increased by a mean of 23% at a time when blood volume expansion averaged 50% (range, 40% to 70%). In four of these eight women, there was no change in clearance despite pregnancy-induced hypervolemia that averaged 50%; however, in the other four clearance substantively increased. In the four women with severe renal impairment who were studied, creatinine clearance was unchanged despite blood volume expansion that averaged 23% (range, 13% to 33%).

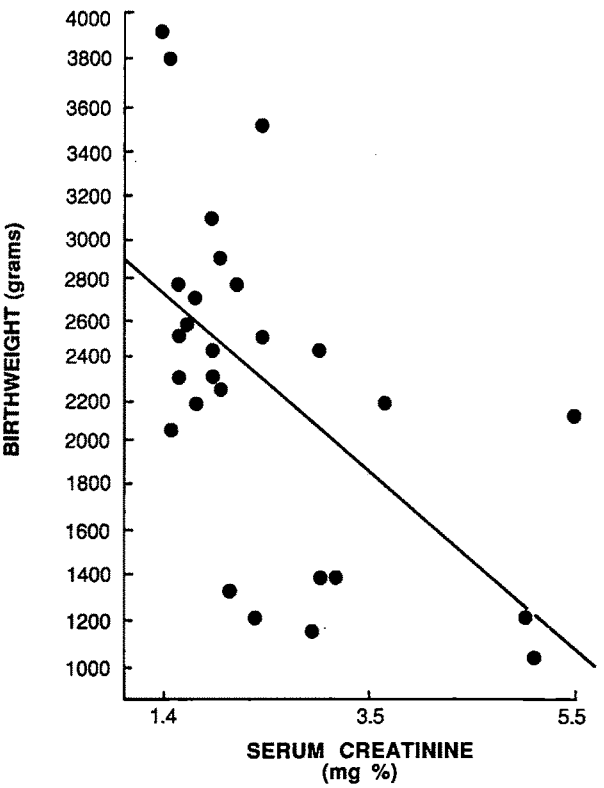

Fig. 1. Comparison of birth weight of 29 live-born infants with maternal serum creatinine concentration (Spearman correlation coefficient = −0.6252; $p = 0.001$).

Comment

Pregnancy in these women with moderate and severe chronic renal insufficiency commonly was complicated by chronic hypertension, preeclampsia, and anemia. Hypertension antedating pregnancy was identified in 68% of these 37 women, and others have reported incidences that range from 23% to 63% in women with mild to moderate disease.[2, 10, 11] Although it is sometimes difficult to identify preeclampsia accurately in women with chronic renal dysfunction, we made this diagnosis clinically in nearly 60%, and found it to be a major source of morbidity, particularly with regard to preterm birth. An important observation was that superimposed preeclampsia developed in 80% of women with chronic hypertension.

It has been reported that 8% to 50% of women with moderate renal insufficiency experience a decline in renal function during pregnancy.[2, 10-13] We documented significant worsening renal function in six women (16%), and perhaps unexpectedly, only one of these had severe dysfunction initially. We followed up these six women for a mean of 5 years; five continued to have worsening renal function and in four of these, dialysis became necessary for end-stage renal disease. It is important that poorly controlled chronic hypertension was implicated frequently in deterioration of renal function. Although the duration of our prepregnancy observation was inadequate to ascertain whether pregnancy-related events actually accelerated renal failure, this did not appear to be the case. Specifically, there were another six women who had stable renal function throughout pregnancy, but in whom deteriorating renal function later developed, and four of these ultimately required dialysis. In both groups of women (i.e., those with and without declining renal function during pregnancy) the mean interval from delivery-to-dialysis was similar (30 versus 39 months). Although some have suggested that women with lupus nephropathy, membranoproliferative glomerulonephritis, and immunoglobulin A and reflux nephropathy are more vulnerable to increasing renal damage during pregnancy,[14] we could not address this because most women now reported had not undergone renal biopsy sampling.

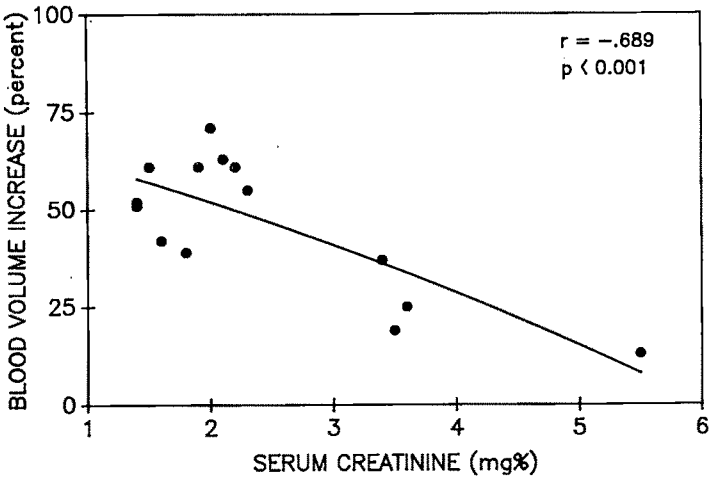

Fig. 2. Blood volume expansion during pregnancy plotted as function of serum creatinine concentration.

The causes of renal dysfunction, however, were known for the six women who had worsening function (Table II), and three of these are from these above-cited categories.

Although maternal complications were common in women now reported, adverse perinatal outcome was not prohibitive. For example, 80% of pregnancies resulted in live-born infants. Six pregnancies either aborted spontaneously or were electively terminated before 26 weeks' gestation. Loss before 26 weeks' gestation was more common in women with severe dysfunction, and two pregnancies were terminated surgically before dialysis in women with end-stage disease. For all women, perinatal mortality was limited to one third-trimester fetal death. Preterm delivery complicated 13 of 32 pregnancies (40%) that reached 26 weeks' gestation, and the mean birth weights in the moderate and severe renal disease groups were 2500 and 1520 gm, respectively. As shown in Fig. 1, birth weight correlated inversely with serum creatinine concentration; however, it was difficult to separate this relationship from chronic hypertension. In women with moderate insufficiency further complicated by chronic hypertension, preterm birth (43%) was more frequent than in normotensive women (10%). Superimposed preeclampsia developed in 80% of chronically hypertensive women and this also was associated with an even higher incidence of preterm birth (57%). It is important that superimposed preeclampsia not only developed earlier in pregnancy, but it tended to be more severe than in women who have normal renal function. Others have reported the incidence of preterm birth in women with chronic renal disease to be about 60%.[2, 10] Finally, hypertension was a common cofactor (73%) in women with fetal growth retardation, and indeed, 40% of infants of chronically hypertensive women were small for gestational age. The overall incidence of perinatal loss in women now reported was 3.2%, which compares favorably with reported figures for women with mild disease that range from 9% to 18%.[10, 12]

These findings confirm those of others that nonpregnant women with moderate to severe renal insufficiency have blood volumes comparable with those of women without renal disease.[15-17] Our observations are remarkably similar to those reported by Eisenberg[15] who used radiochromium-labeled erythrocytes to estimate blood volume in eight men with the nephrotic syndrome whose serum creatinine values ranged from 1.5 to 3.6 mg/dl. It is important that we found also that women with chronic renal insufficiency usually have normal blood volume expansion in response to pregnancy. This increase, which averages about 50% in normal women,[8] was almost identical in women with moderate disease; however, it was attenuated significantly in those with severe disease. Specifically, whereas pregnancy-induced hypervolemia averaged 51% in women with moderate renal impairment, it was only 23% in those with severe disease. As shown in Fig. 2, the magnitude of volume expansion was inversely proportional to serum creatinine.

An intriguing finding was that most of these women responded to pregnancy with increased erythropoiesis. Although most were anemic when not pregnant, mean red cell mass increased 23% during pregnancy. As with blood volume expansion, this corresponded to the degree of renal impairment, and erythrocyte mass expansion related inversely to the serum creatinine. Because red cell mass expansion was less pronounced than

blood volume expansion, preexisting anemia usually was intensified. Pregnancy-induced erythropoiesis presumably is related to increased erythropoietin production,[18, 19] but this has not been fully evaluated and we can only speculate that these women with chronic renal insufficiency had augmented erythropoietin secretion.

Although Katz[11] has reported that the glomerular filtration rate and effective renal plasma flow increased incrementally in pregnancy complicated by mild renal disease, and similar to normal pregnancy, only one of 33 women that he described had a serum creatinine level >1.4 mg/dl. It is important that hypertension may cause further nephron damage, ultimately leading to further glomerular injury.[20] From the current study it is apparent that augmentation of glomerular filtration in these women with moderate to severe renal insufficiency was not solely a result of pregnancy-induced hypervolemia. When paired blood volume and creatinine clearance determinations during pregnancy and again post partum were compared, despite an average volume expansion of 50% in eight women with moderate dysfunction, the glomerular filtration rate increased by a mean of only 23%. Indeed four of these eight women had no increase in their glomerular filtration rate. None of the four women with severe renal impairment had augmented glomerular filtration during pregnancy. These latter findings are supportive of the theory that increased glomerular filtration is mediated at least partially by pregnancy-induced vasodilation.[21-22] In this scheme, because severe renal insufficiency is characterized by maximal vasodilation, augmentation of renal function as a result of pregnancy is not possible. It is important that it has been shown that severe hypertension may be harmful to these already-damaged nephrons, leading to further glomerular injury.

Epidemiology of preeclampsia and eclampsia in the United States, 1979-1986

Audrey F. Saftlas, PhD, David R. Olson, PhD, Adele L. Franks, MD, Hani K. Atrash, MD, and Robert Pokras, MS

Atlanta, Georgia

Preeclampsia and eclampsia continue to be among the leading causes of maternal death. However, national estimates of the occurrence of these conditions have not been available. To derive national rates of preeclampsia and eclampsia and to characterize the women at highest risk of the development of these conditions, we analyzed data from the National Hospital Discharge Survey for the years 1979 through 1986. We found that 26 per 1000 births during this period were complicated by preeclampsia and 0.56 per 1000 births were complicated by eclampsia. The rate of mild or unspecified preeclampsia remained constant over the study period. In contrast, the rate of severe preeclampsia increased sharply and the rate of eclampsia declined by 36%. Maternal age <20 years old was the strongest risk factor for both preeclampsia and eclampsia. These data indicate a need for improved prenatal care among teenagers. (AM J OBSTET GYNECOL 1990;163:460-5.)

Key words: Preeclampsia, eclampsia, pregnancy-induced hypertension, maternal morbidity

Preeclampsia and eclampsia continue to be important public health problems in the United States. In recent studies, these conditions were shown to be the second leading cause of maternal death[1, 2] and were associated with increased risk of abruptio placentae,[3] disseminated intravascular coagulation, acute renal failure, and cerebral hemorrhage.[4] In addition, preeclampsia and eclampsia reduce uteroplacental perfusion, which places the fetus at high risk of intrauterine growth retardation, preterm birth, and perinatal mortality.[4, 5] However, proper obstetric care and antenatal fetal assessment can minimize the maternal and fetal morbidity and mortality from these conditions.[4]

Although preeclampsia and eclampsia have been studied extensively worldwide, their cause remains unknown. Hypotheses have focused on numerous etiologic factors including the role of endogenous hormones,[6] nutrition,[7, 8] immunologic factors,[9] and family history of these conditions.[10] However, few well controlled epidemiologic studies of risk factors for preeclampsia and eclampsia have been conducted.

Most estimates of the incidence of preeclampsia and of eclampsia in the United States have been made on the basis of nonrepresentative clinical series or multicenter studies. The incidence of these conditions is generally given as 5% to 7% of all deliveries.[4] To estimate the incidence of preeclampsia and eclampsia on a national level, we analyzed data from a representative sample of hospital discharge records nationwide. In addition, we evaluated demographic risk factors for preeclampsia and eclampsia and trends in occurrence over an 8-year period from 1979 through 1986.

Material and methods

The Committee on Terminology of the American College of Obstetricians and Gynecologists defines preeclampsia as hypertension induced by pregnancy after 20 weeks' gestation concurrent with proteinuria or edema or both.[11] Hypertension is defined as a diastolic pressure of at least 90 mm Hg, a systolic pressure of at least 140 mm Hg, or a rise from baseline of 15 mm Hg diastolic pressure or 30 mm Hg systolic pressure. The elevated blood pressure readings must occur on at least two occasions at least 6 hours apart. Eclampsia, a severe complication of preeclampsia, is defined as the occurrence of convulsions unrelated to coincidental neurologic disease in a woman with preeclampsia.

Data for this study were obtained from the National Hospital Discharge Survey, conducted by the National Center for Health Statistics. Since 1965 this survey has obtained a nationally representative sample of discharge records from nonfederal short-stay hospitals in the United States.[12] Each year approximately 200,000 patient records are abstracted from approximately 400 hospitals and weighted to represent all such hospital discharges nationwide.[12] Up to seven discharge diagnoses and four operative procedures are abstracted

from the face sheet of each hospital record sampled and coded according to the *International Classification of Diseases,* 9th Revision, Clinical Modification (ICD-9-CM). Available data items include date of birth, sex, race, marital status, expected source of payment for hospitalization, and geographic region of residence in the United States.

The study population consisted of all sampled women who were delivered of a stillborn or live-born infant in the hospital during 1979 through 1986. Incidence rates were calculated per 1000 deliveries for mild or unspecified preeclampsia (code 642.4), severe preeclampsia (code 642.5), and eclampsia (code 642.6). We do not discuss preeclampsia and eclampsia superimposed on preexisting hypertension because our analyses showed that demographic risk factors for these conditions are more like those for chronic hypertension than those for de novo hypertension during pregnancy. For some analyses, when severity of preeclampsia was not specified, categories were combined. Rate ratios were also calculated to evaluate the risk of preeclampsia and eclampsia associated with several demographic variables. To evaluate the trend in the rate of eclampsia during the study period, we calculated average annual age-adjusted rates for two time periods: 1979 through 1982 and 1983 through 1986.

We used direct standardization to adjust incidence rates for the effects of age and race.[13] The standard

population consisted of all women in the survey who were delivered of a stillborn or live-born infant during the 8-year study period.

With the use of the computer program SESUDAAN (Research Triangle Institute, Research Triangle Park, N.C.), we calculated crude and adjusted incidence rates and their corresponding SE, taking into account the complex multistage sampling design of the National Hospital Discharge Survey.[14] For computing SE, we used a first-order Taylor series linearization.[15] We also applied Taylor series expansion to rate ratios and calculated 95% confidence intervals with SESUDAAN to estimate the variance and covariance terms. Weighted linear regression was used to test for linear trend in rates of preeclampsia over the 8-year period.[16] Rates and rate ratios are given only for weighted numerators of ≥5000 discharges because estimates of <5000 are considered unreliable.[12]

After stratification by type of delivery, we also estimated the mean length of hospital stay for women whose pregnancies were normotensive and for those whose pregnancies were complicated by preeclampsia or eclampsia.

Results

An average of 100,200 deliveries were complicated by preeclampsia during each year of the 8-year study period (Table I). The average annual incidence rate was 26 cases per 1000 deliveries. The rate of preeclampsia fluctuated only slightly over the study period. Whereas the rate of mild or unspecified preeclampsia decreased slightly during the study period, the rate of severe preeclampsia increased sharply from 2.9 cases per 1000 deliveries in 1984 to 5.2 cases per 1000 deliveries in 1986 (test for linear trend, $p < 0.01$). This increase was observed among women of both racial groups (data not shown).

Fig. 1 shows the trend in age-adjusted rates of preeclampsia by racial group over the study period. The

rate for women of black and other minority races appears to be declining (test for linear trend, $p = 0.06$), whereas the rate for white women has been relatively stable (test for linear trend, $p = 0.27$). Between 1979 and 1985 the incidence of preeclampsia among women of black and other minority races was higher than that among white women; however, rates for the two racial groups crossed over in 1986 when the rate was 28.3 cases per 1000 deliveries for white women and 27.6 cases per 1000 deliveries for women of black and other minority races. The greatest racial disparity in the rate of preeclampsia occurred in 1979 and 1980; however, these differences were of borderline statistical significance ($0.10 > p > 0.05$).

Table II shows by race, the number of cases, rates, and rate ratios for preeclampsia associated with selected demographic characteristics. For the study period, the risk of preeclampsia was most strongly associated with maternal age in a reverse J-shaped curve. Women under the age of 15 years had a 2.8-fold higher risk of the development of preeclampsia than did women ages 30 to 34 years old. Risk decreased with age until age 35 years when it increased significantly for women of black and other minority races.

Stratification by marital status showed that single women were at significantly greater risk of the development of preeclampsia (rate ratio = 1.29) than were married women. When rate ratios were examined by geographic region, we found that white women who resided in the South and West had a significantly higher rate of preeclampsia than did white women who resided in the Northeast. In contrast, little regional variation in the risk of preeclampsia was noted among women of black and other minority races. Analysis by primary source of expected payment for hospitalization showed no significant difference in the risk of preeclampsia among women on Medicaid than among women who had private health insurance (data not shown).

Eclampsia occurred much less frequently than did preeclampsia. An average of 2000 deliveries were complicated by eclampsia annually during the study period, for an average annual rate of 0.56 cases per 1000 deliveries (data not shown). The rate decreased by 36% from 0.68 cases per 1000 deliveries for 1979 through 1982 to 0.43 cases per 1000 deliveries during 1983 through 1986.

We also calculated rates and rate ratios for the occurrence of eclampsia in different subgroups for the period 1979 through 1986 (Table III). Maternal age was most strongly associated with risk of eclampsia. Women under the age of 20 years had nearly a fivefold greater risk of the development of eclampsia than did women 20 years of age or older. Race and marital status were not significantly associated with risk of preeclampsia. Because of the low number of women with eclampsia, we were not able to evaluate variations in rates by region or by expected source of payment.

Mean length of stay in the hospital was determined for women who had preeclampsia or eclampsia and for those who gave birth but remained normotensive throughout pregnancy (Table IV). All estimates were stratified according to whether the birth was vaginal or by cesarean section. It was necessary to stratify by type of delivery because women with preeclampsia or eclampsia were 2.4 times more likely to have had a cesarean section (rate = 46.5%) than were normotensive women (rate = 19.1%).

The mean length of stay decreased over the 8-year study period for women in all categories. Among women who had a vaginal delivery, those with preeclampsia or eclampsia were hospitalized an average of 1.5 days longer than were normotensive women; among women who had a cesarean birth, those with preeclampsia or eclampsia were hospitalized an average of 1.8 days longer than were normotensive women.

Comment

Analysis of National Hospital Discharge Survey data indicates that preeclampsia complicated 26 per 1000 deliveries or 2.6% of all births from 1979 to 1986. This rate is lower than that reported by most hospital-based studies. The higher rates may be attributable to the many high-risk patients in referral hospitals. Because our rate was calculated by use of a representative sample of hospital discharge records from across the United States, it more accurately represents the rate for the total U.S. population. The rate of preeclampsia we found is similar to that reported by the National Natality Survey (Unpublished data) and two other clinic

Preeclampsia or eclampsia	8.7	8.7	8.2	7.0	7.6	7.0	6.9	6.1

and hospital-based studies[8, 17] but is lower than the rates of preeclampsia of 4.5% and 11.2% reported for whites and blacks, respectively, by the U.S. Collaborative Perinatal Study.[18]

Eclampsia complicated 0.56 per 1000 deliveries over the 8-year study period. Although this rate is lower than those reported by other hospital-based studies in the United States,[4] it is only slightly less than rates estimated by the U.S. Collaborative Perinatal Study for the years 1959 through 1965 (white women, 0.61 cases per 1000 deliveries; black women, 0.75 cases per 1000 deliveries).[18] In contrast, the eclampsia rate we found is two times higher than the rate of 0.27 per 1000 deliveries reported for the population of Sweden for 1976 through 1980.[19] The low rate of eclampsia in Sweden was attributed to the early and regular prenatal care received by the majority of Swedish women.

We found young maternal age to be the strongest risk factor for both preeclampsia and eclampsia; teenagers were at significantly higher risk than were women 25 to 34 years of age. This finding is consistent with the clinical observation that preeclampsia is primarily a condition of young primigravid women.[4] Our findings are also in accord with those of Zlatnik and Burmeister[8] who found that young maternal age was significantly associated with risk of preeclampsia, even after controlling for the effects of parity and ponderal index. However, other studies have reported that the rate of preeclampsia and eclampsia increased with maternal age, before and after controlling for parity.[18, 20, 21] Because we lacked data on parity we could not evaluate the independent effects of maternal age and parity. Additional studies are needed to clarify the role of parity and age on the risk of preeclampsia.

Race was not a significant risk factor for either preeclampsia or eclampsia. From 1979 to 1986 the rate of preeclampsia decreased among women of black and other minority races but varied little among white women. By 1986, rates for the two groups were virtually equivalent. We were unable to identify any subgroup of black and other minority women that could account for the decrease in rate over time; decreases were found for all geographic areas, payment categories, marital status groups, and age groups, except for women ages 20 to 24 years and 35 years or older. Several studies have reported higher rates of preeclampsia and eclampsia among black women than among white women in the United States.[17, 18] Black American women have a higher rate of chronic hypertension than that of white women; thus the higher rates of preeclampsia that we found for minority women early in the study period may have been biased by misclassification of chronic hypertension as preeclampsia.

Unmarried women had a significantly higher rate of preeclampsia than that of married women. However, most other studies have reported no difference in risk by marital status. Our finding may be a result of a higher proportion of primiparous women among the unmarried.

Although race was not a statistically significant risk factor for either preeclampsia or eclampsia, proportionately more women of black and other minority races were under 20 years old and unmarried at the time of childbirth than were white women. Thus the burden of illness from preeclampsia and eclampsia is greater among minority women.

Women whose hospital stays were financed by Medicaid were no more likely to have preeclampsia than were women who had private insurance. With the assumption that women who use Medicaid and women who have private insurance represent two distinct socioeconomic groups, we observed no difference in risk by socioeconomic status. This finding is consistent with that of a Scottish study in which the incidence of preeclampsia did not differ significantly among five social classes.[22]

Our finding of a significantly higher rate of preeclampsia among white women who resided in the South and West compared with those who resided in the Northeast is difficult to explain, particularly because there was little regional variation in the rate among black and other minority women. Nevertheless, these regional differences in the rate of preeclampsia among white women could reflect regional variation in diagnostic practice or true regional differences in the rate of this condition.

We found that the rate of eclampsia decreased over the 8-year study period, whereas the rate of severe preeclampsia was relatively constant from 1979 to 1984 and then sharply increased. Although we cannot be sure of whether these trends are real, the increase in incidence of severe preeclampsia could be a consequence of changes in diagnosis of this condition. Diagnostic-related groups instituted in 1984 may have prompted physicians to provide more accurate reporting of severe preeclampsia or to overdiagnose the condition. When the categories of preeclampsia were combined the rate of preeclampsia varied little over the 8-year study period, which suggests that perhaps more cases of mild or unspecified preeclampsia after 1984 were classified as severe. Because eclamptic convulsions are so dramatic, this diagnosis is rarely missed. Thus we believe that the decline in the rate of eclampsia reflects improved antenatal management of women with preeclampsia. However, the decline in the number of women with eclampsia is not sufficient to explain the increase in the rate of severe preeclampsia.

Women with preeclampsia or eclampsia stayed in the hospital substantially longer than did normotensive women, regardless of method of delivery. This finding has economic implications. Given the longer hospital stay and high rate of cesarean section among women with these conditions, an excess of 217,700 hospital days for delivery admissions in 1986 are attributable to preeclampsia and eclampsia.

Our analysis is limited by the lack of data on important variables such as parity, the inability to distinguish any racial or ethnic groups among women of minority races, and the lack of standardized definitions of preeclampsia among physicians. The Committee on Terminology's criteria[11] for preeclampsia is one of several used by researchers when studying this condition. For this reason, researchers agree that a standardized, international definiton of preeclampsia is necessary. Despite these limitations, we found the National Hospital Discharge Survey to be a good data source to describe the epidemiology of preeclampsia and eclampsia.

Our data indicate that eclampsia develops in approximately 2000 women per year, although most cases of eclampsia are considred preventable with good obstetric care. Teenagers are at highest risk of eclampsia and are also more likely than other women not to receive prenatal care.[23] However, for a given woman, whether eclampsia can be attributed to inadequate prenatal care remains unknown. Case reviews and epidemiologic studies of eclampsia should be undertaken to address this issue directly so that public health recommendations can be made. In addition, well designed epidemiologic studies are needed to determine risk factors for preeclampsia that will identify women at high risk of the development of this condition and lead to risk reduction strategies.

Transvaginal ultrasonographic detection of congenital anomalies in the first trimester

Mark T. Cullen, MD, Jacqueline Green, RDMS, John Whetham, MD, Carolyne Salafia, MD, Sandro Gabrielli, MD, and John C. Hobbins, MD

New Haven, Connecticut

Transvaginal ultrasonography enables detailed visualization of the first-trimester pregnancy. Thirty-three structural anomalies have been diagnosed in the first trimester of pregnancy during a 2-year study period. An understanding of normal embryonic development is essential before attempting diagnosis in this gestational period. (AM J OBSTET GYNECOL 1990;163:466-76.)

Key words: Pregnancy, prenatal diagnosis, first trimester, transvaginal ultrasonography

The development of transvaginal ultrasonography enables earlier and more detailed examination of the first-trimester conceptus.[1-3] Enhanced visualization and an understanding of normal embryologic development as depicted by ultrasound may allow the detection of congenital anomalies in the first trimester. Early diagnosis alleviates the morbidity and expense associated with second-trimester abortion, as well as the anxiety engendered by waiting for testing at a later period. We present our experience with the antenatal detection of congenital anomalies in the first trimester and suggest some limitations of this practice.

Material and methods

During a 2-year study period ending February 1989, 805 ultrasonographic examinations were performed on 622 first-trimester fetuses at the Perinatal Unit of Yale University School of Medicine. Patients were referred as part of an ongoing evaluation of the efficacy of prenatal diagnosis in the first trimester. Criteria for entry into the study included a gestational age of 13 menstrual weeks or less with a live embryo at the time of the examination. Scans were repeated in gestations <10 weeks.

Ultrasonographic examinations were performed abdominally (General Electric 3000, Milwaukee; Corometrics Aloka 280 SL, Wallingford, Conn.) and transvaginally (Advanced Technology Laboratories UM-4, Bothell, Wash.). All sonograms were performed and videotapes subsequently reviewed by at least two of the authors. The assessment included a complete anatomic survey including evaluation of the ventral and dorsal wall, calvarium, face, extremities, placenta, and umbilical cord. Most patients underwent a complete anatomic survey at 16 to 18 weeks' gestation.

Gestational age was calculated from last menstrual period. If a discrepancy of greater than plus or minus 5 days was observed, the ultrasound assessment was used. In this study all gestational ages were expressed in menstrual weeks.

Structural anomalies were grouped by the most significant anatomic lesion. Embryos with isolated choroid plexus cysts were not included in this study.

In cases of pregnancy termination, gentle embryo extraction was performed. Pathologic examination was performed by a pathologist experienced in developmental embryology.

Results

Thirty-three embryos were identified as having structural anomalies in the 622 patients studied (0.5%). Table I lists the structural anomalies found at pathologic examination, ultrasound findings, gestational age at the time of diagnosis, and pregnancy outcome. The indications for referral of the fetuses with a detected anomaly were as follows: before chorionic villus sampling, 11; maternal diabetes, 2; history of an anomaly in a previous pregnancy, 2; pregnancy dating, 11; and a suspicious scan at another institution, 7 cases.

The outcome of each pregnancy was available in all cases in which an anomaly was suspected. Gestational ages at the time of diagnosis ranged from 8 to 13 weeks (mean, 11 weeks). Although not all fetuses that had a normal scan were reviewed, the referral population is localized to New Haven, where a missed anomaly is routinely reported by the community.

Four ventral wall defects were diagnosed, five neural tube defects, five urinary tract abnormalities, nineteen

15-33	Cystic hygroma (n = 19) (isolated)	10-12	Same	NSVD resolved (n = 2); TOP and death (n = 19)

TOP, Termination of pregnancy; *PG,* prostaglandin abortion; *NSVD,* normal spontaneous vaginal delivery.

isolated cystic hygromas, and two anomalies of the cord or yolk sac were seen. In two cases there were more than one significant anomaly.

Of the 33 defects that were diagnosed, 23 patients had elective first-trimester abortions, four had spontaneous fetal deaths, one underwent a prostaglandin abortion in the second trimester, and five were delivered at term.

Pathologic confirmation of terminated specimens was accomplished in all but three cases. In cases 11 and 14, the nonviable embryos were macerated; however, embryoscopic verification[4] was possible in case 14. In case 10 the specimen was inadequate for pathologic examination as a result of the abortion procedure. There were three instances in which the lesion resolved: one large umbilical cord cyst and two cystic hygromas.

Comment

Prenatal diagnosis of congenital anomalies has advanced the practice of modern obstetrics. Diagnosis in the first trimester is advantageous because it lessens the anxiety and morbidity of second-trimester diagnosis and abortion.

Technical advances in ultrasonography and the advent of transvaginal ultrasonography now afford superior visualization of the embryo.[2, 3] Improved resolution, in conjunction with a growing interest in early diagnosis, which includes ultrasonography, chorionic villus sampling, and amniocentesis, will lead to a greater number of embryos undergoing an ultrasound examination. With a higher incidence of chromosomal abnormalities in the first trimester[5] and a known association of structural anomalies with aneuploidy, we expect that more anomalies will be identified in the first trimester as more scans are performed.

Green and Hobbins[1] and Timor-Tritsch et al.[3] have recently described the normal ultrasonographic appearance of the developing embryo throughout the first trimester. These data afford the background necessary for ultrasonography to be used for the detection of congenital anomalies. The series presented here and case reports in the literature illustrate the utility of ultrasonography in first-trimester diagnosis.

A review of developmental anatomy and diagnostic criteria and limitations for specific anomalies are discussed below by anatomic location.

Head and neck. The intracranial anatomy initially appears as a single ventricle with the rhombencephalon at 8 weeks. The large posterior position of the rhombencephalon (Fig. 1) should not be confused with a Dandy-Walker malformation. The falx cerebri can be seen dividing the midline with two prominent choroid plexuses at 9 weeks, whereas calcification of the calvarium and visualization of the cerebellum does not become apparent until the tenth week. The ventricles, with the prominent choroid plexus are seen filling the calvarium throughout the first trimester. A small amount of cortex can be seen at the periphery by the end of the twelfth week. Because the corpus collosum, which is superior to the third ventricle, does not fully develop until the second trimester, the third ventricle may be seen at a level higher than the thalamus (Fig. 2). The antenatal diagnosis of hydrocephaly without craniomegaly is not likely due to the large relative proportions of the lateral ventricles to the calvarium.

From the above observations of normal neuroanatomic development, it is clear that anencephaly (Fig. 3), exencephaly (Figs. 4 and 5), encephalocele and acrania cannot be diagnosed until after 10 weeks when the calvarium is calcified.[6] These conditions are illustrated in cases 2, 7, 9, and 10. Exencephaly was diagnosed by the presence of an irregular mass that represented disorganized neural and vascular tissue with the absence of a calvarium. Anencephaly, which is thought to be a progression from exencephaly through mechanical abrasion, might appear at a later gestation. In embryos with acrania, normal cerebral cortex is seen without a bony calvarium. The diagnosis of an encephalocele should be considered when a calcified cranium is seen with protruding neural tissue. Choroid plexus cysts appear as well-defined sonolucencies in the choroid plexus and are occasionally seen in the first trimester.[1] The significance of this finding is currently unclear.

Face. The mandible and maxilla are visualized at 10 weeks, well after the seventh week when there is complete fusion of the midline structures. There have been no reported cases in which the prenatal diagnosis of midline clefting has been made in the first trimester, although it should be possible. The external ears are seen at 8 weeks. Low-set ears were apparent in case 4 (Fig. 6), which was associated with multiple anomalies and trisomy 13. Case 9 demonstrates hypotelorism (Fig. 5) in a case with a neural tube defect. Recently we have examined a woman with class D diabetes whose embryo was scanned at 10.5 weeks, before long bone mineralization, and appeared normal. At 18 weeks the fetus was found to have micrognathia and mesomelic limb dysplasia.

Spine. The dorsal wall can be seen in the sixth week. Closure of the neural pore and calcification of the lamina of the spine do not occur until 6 and 10 weeks, respectively, at which time it is possible to diagnose some neural tube defects.[7] Kyphoscoliosis is demonstrated in case 9 by observing the misalignment of the lamina and spinal body.

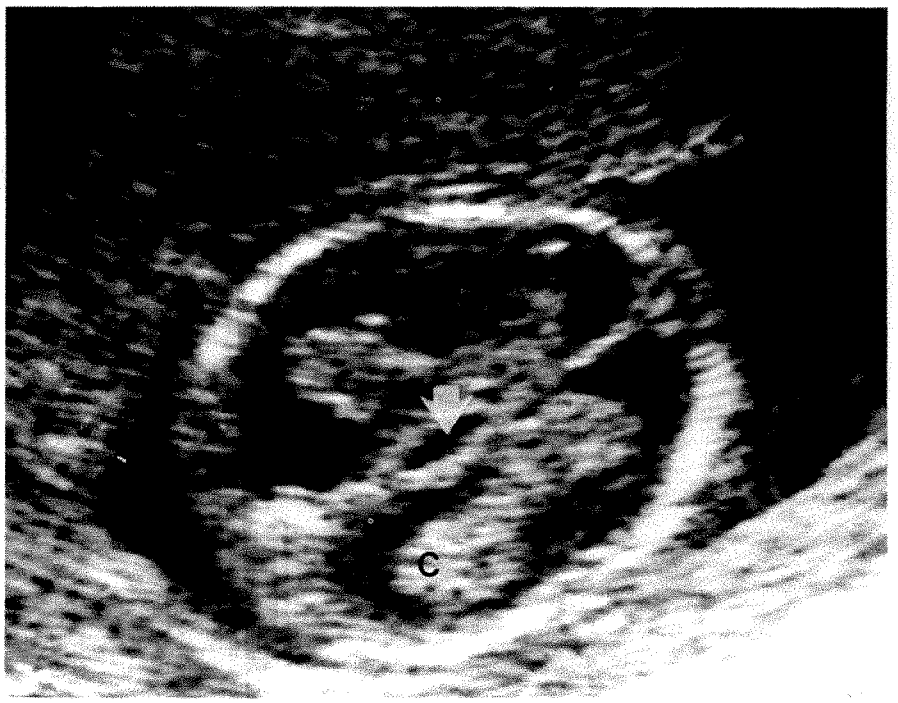

Fig. 2. Transverse scan of normal 12-week embryo head above level of thalamus. The prominent choroid plexus **(C)** is seen in the large lateral ventricular space. Third ventricle *(arrow)* is shown.

Fig. 3. Transverse scan of head at level of orbits in 12-week embryo with anencephaly.

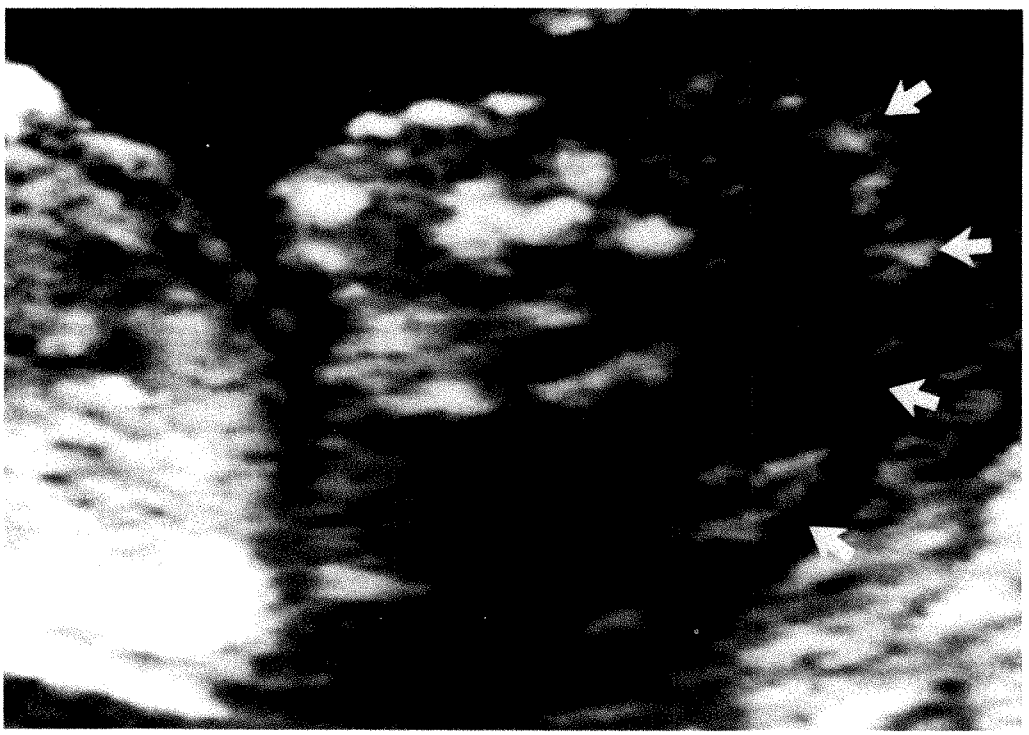

Fig. 4. Sagittal scan in 11-week pregnancy with exencephaly. Disorganized neural tissue *(arrows)* and absence of the calvarium are noted.

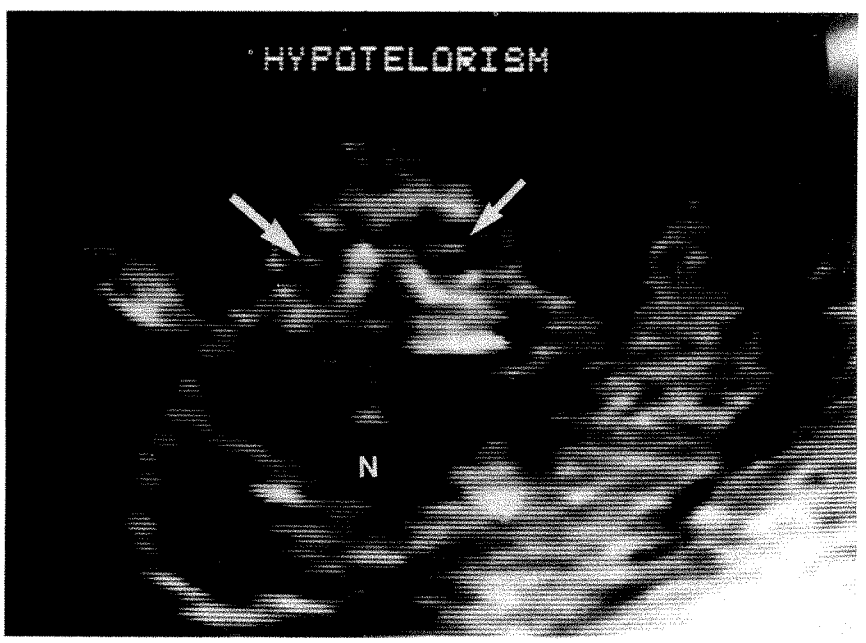

Fig. 5. Transverse scan at level of orbits showing hypotelorism *(arrows)* in a 12-week embryo with exencephaly. Disorganized neural tissue *(N)* is shown.

Ventral wall. The ventral wall of the developing embryo is apparent at 6 weeks. Physiologic herniation of the bowel into the proximal umbilical cord can be demonstrated between 8 and 11 weeks as a thickening of the cord insertion.[8-10] If the herniation is noted after 12 weeks an omphalocele should be suspected. Two omphaloceles were diagnosed in this series, both of which were associated with other anomalies. In case 3 (Fig. 7), anterior abdominal wall edema could have impeded the bowel from returning to the abdomen. In

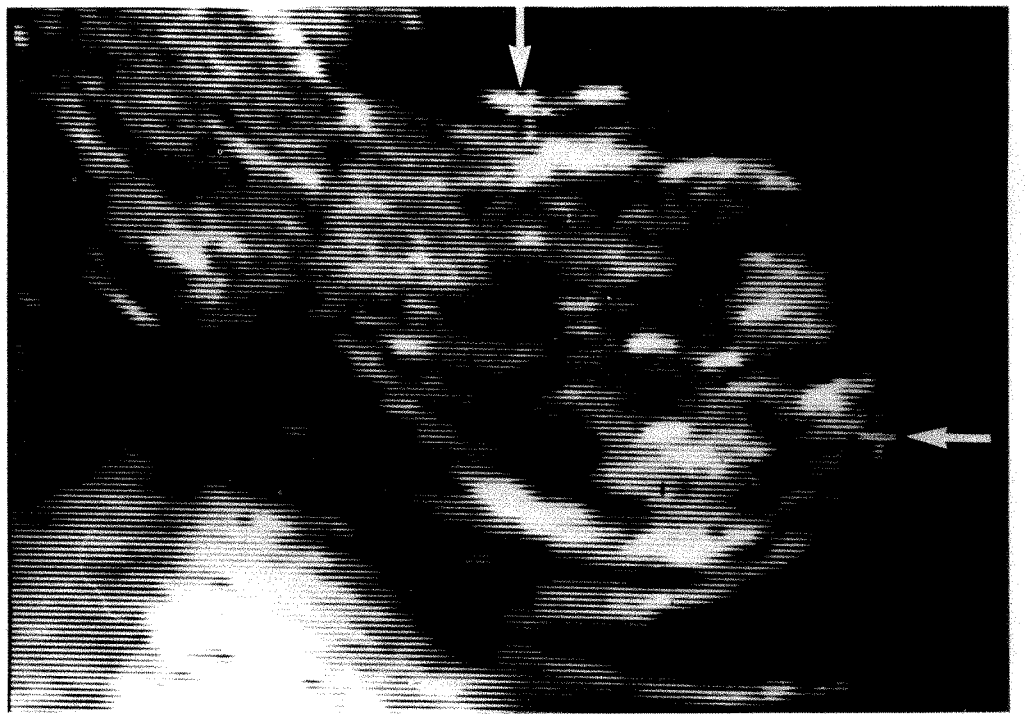

Fig. 6. Low-set ears are seen in this 12-week conceptus with nuchal cystic hygroma and trisomy 13.

case 12, hydronephrosis and an omphalocele were visualized. A large cystic dilatation in the cord represented dilated bowel. A gastroschisis (Fig. 8) was identifiable as a lateral anterior wall defect with bowel herniation remote from the cord insertion. A large ventral wall defect classified as a lateral folding defect was diagnosed in our first case based on the close proximity of the embryo to the placenta and wide short cystic cord. Since this series, we have experience with a case of gastroschisis, which was discovered at 10 weeks.

Cystic hygromas. Cystic hygromas are fluid-filled sacculations of the lateral neck and nuchal region that result from lymphatic dysplasia.[11-14] Our experience has shown that these are the most common anomaly in the first trimester. We have recently described 30 cases in a combined series,[11] grouping them by anatomic location as lateral nuchal, posterior nuchal (Fig. 9), or either location associated with hydrops (Fig. 10). The incidence of aneuploidy in this series was 53% and was not related to the anatomic location or the presence of septation. This is in contrast to reports by other authors.[14] These lesions must be differentiated from defects in the fetal spine and calvarium as well as close proximity of the embryo to the amnion and yolk sac. Since that report we have identified an embryo at 11 weeks with axillary and nuchal hygroma.

Extremities and digits. Limb paddles can be seen at 7 weeks with the long bones appearing to calcify at 10 weeks. Distinct digits are easily delineated at 11 weeks. In case 4, postaxial polydactyly was discovered retrospectively on videotape review in a fetus with cystic hygroma. The polydactyly was discovered during embryoscopic verification before termination. A case of a short limb dysplasia has been described in the first trimester.[15] In the patient with diabetes with micrognathia described in the section on facial anomalies, mesomelic dysplasia was also present and not apparent at 10.5 weeks. At that time the extremities appeared normal in size and morphologic features but were not yet mineralized. It is currently not known when specific limb dysplasias manifest.

Heart. A four-chamber view of the heart can be obtained as early as 11 weeks. Recently an atrioventricular canal defect with complete heart block was reported.[16] Despite this promising report, alterations in chamber size may not be apparent until later in pregnancy, making diagnosis of subtler defects difficult if not impossible. We are aware of two cases in which congenital heart defects were not seen in the first trimester. In one fetus at risk for Uhls syndrome, characterized by a parchmentlike right ventricle, the four-chamber view appeared normal at 13 weeks. The pregnancy was subsequently terminated for maternal reasons. Pathologic examination of the heart showed the ventricular defect was present. In a second case, transposition of the great vessels and pulmonary stenosis were not appreciated at 10 and 13 weeks but were discovered on a follow-up ultrasonographic examination at 22 weeks. Currently the sensitivity of transvaginal ultrasonography for the examination of the early heart is unclear.

Fig. 7. Transverse scan at level of abdomen shows omphalocele and hydronephrotic kidney *(arrow)*.

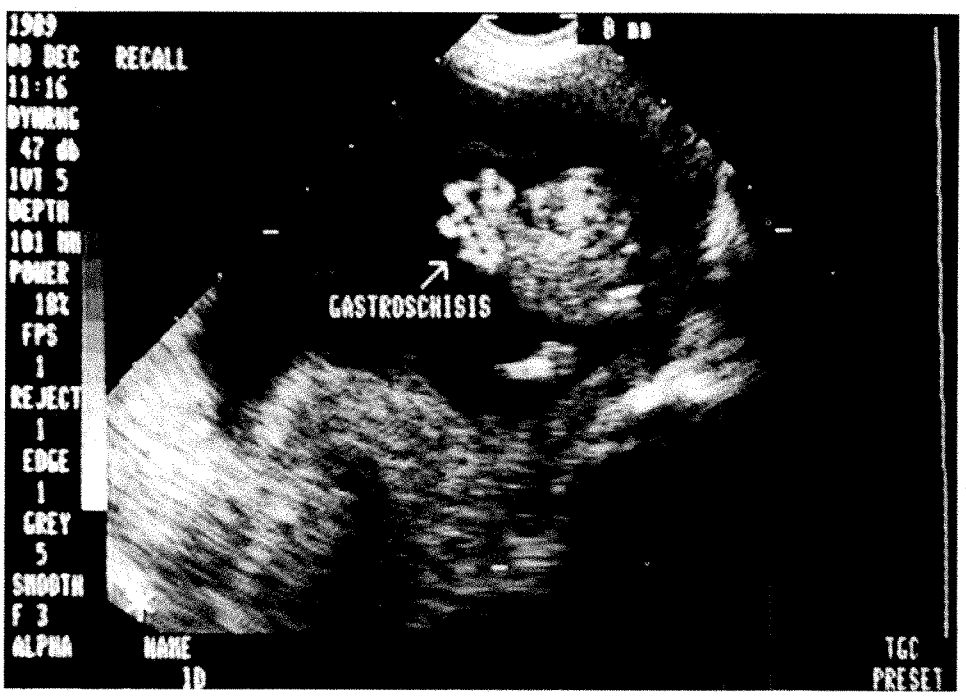

Fig. 8. Transverse scan of abdomen in 11-week embryo with gastroschisis.

Genital urinary. Kidneys and bladder may be imaged by 10 weeks. In case 13, the embryo had weekly examinations beginning at 8 weeks; at 11 weeks the renal parenchyma was noted to be hyperechoic with no obvious dilatation of the bladder. The newborn was delivered at term. A neonatal scan was performed and confirmed the suspected diagnosis of cystic dysplastic kidney disease. This series (cases 3, 5, 6, and 12) and the literature[17, 18] demonstrate the ability of ultrasonography to diagnose obstructive uropathies in the first

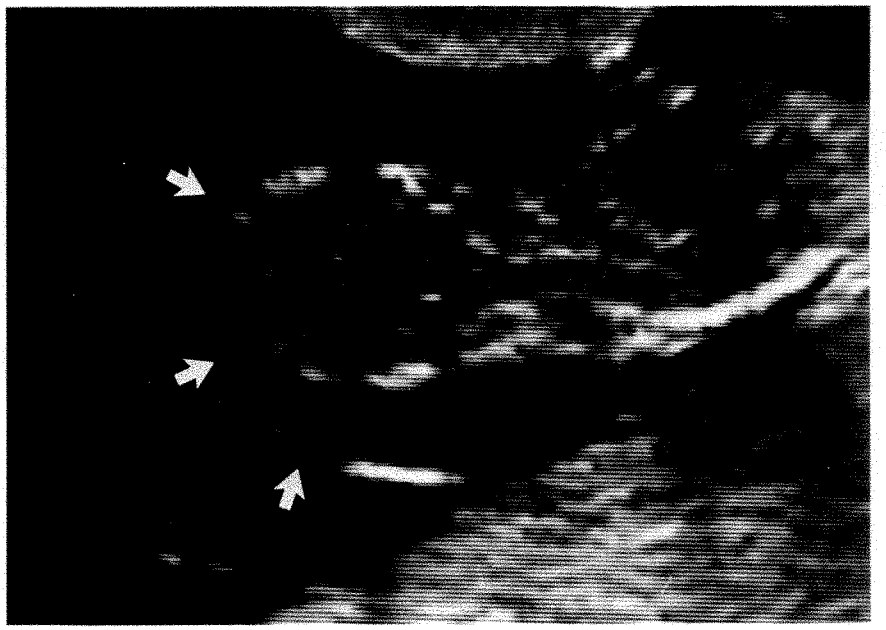

Fig. 9. Oblique scan in 11-week embryo with posterior nuchal cystic hygroma *(arrows)* in embryo with trisomy 18.

trimester. These have included megacystitis (Fig. 11) and hydronephrosis (Fig. 7). Dilatation of the bladder was diagnosed by the demonstration of a large sonolucent cystic structure in the fetal pelvis without the presence of a normal bladder. Pathologic examination was consistent with megacystitis. The early detection of renal agenesis has not been reported but might be possible by 11 weeks by nonvisualization of the kidneys and bladder. Care must be exercised not to confuse the adrenal glands with the kidneys. The adrenals are of similar size at this gestation but, unlike the kidneys, have a sonolucent cortex and dense medullary region. Anatomic differentiation of the fetal genitalia is not complete until 11 weeks, when the male phallus often can be identified. No abnormalities of this system have been recorded to date in the first trimester.

Gastrointestinal. The stomach is seen as a well-delineated hypoechoic structure inferior to the diaphragm on the left side of the abdomen at 10 to 11 weeks. Esophageal and duodenal atresia have not been reported despite the fact that many aneuploid fetuses have undergone ultrasound examinations at the time of chorionic villus sampling. We are currently following a aneuploid fetus with a classic double bubble that was detected at 13 weeks' gestation.

Placenta, umbilical cord, and yolk sac. The chorion frondosum is well demarcated at 7 weeks. A partial mole has been reported in the first trimester.[19] The placenta was noted to have multiple small sonolucent areas. Cord abnormalities in this series included a transient umbilical cord cyst that resolved without sequelae and a short cord associated with a ventral wall folding defect. In case 14, a large yolk sac measuring 2 × 2 cm (normal 0.5 × 0.5 cm) was demonstrated at 8 weeks. Fetal death was observed several days later. The embryo appeared normal by embryoscopy. Small solid yolk sacs have been observed and can be associated with impending fetal death.[1]

Twins. Identification of twins is possible as early as 5 weeks. Case 9 demonstrates the identification of monoamniotic twins, one exencephalic and the other normal. Twin reverse arterial perfusion syndrome has been reported[20] as well as conjoined twins.[21]

With the enhanced visualization afforded by transvaginal ultrasonography, care must be taken not to misinterpret normal variations in anatomy, or artifacts. Fig. 12 shows an echogenic "bowel mass" in an 11-week fetus. This echogenic structure is commonly seen and is the appearance of the normal bowel returning to the fetal abdomen from the physiologic herniation in the cord. We have also seen an echogenic area that appeared to be in the frontal lobe in the calvarium in an 11-week euploid embryo with cystic hygromas. Both the hygroma and "lesion" subsequently resolved. The newborn was normal.

This study demonstrates the applicability of ultrasonography for the antenatal diagnosis of structural anomalies in the first trimester of pregnancy and illus-

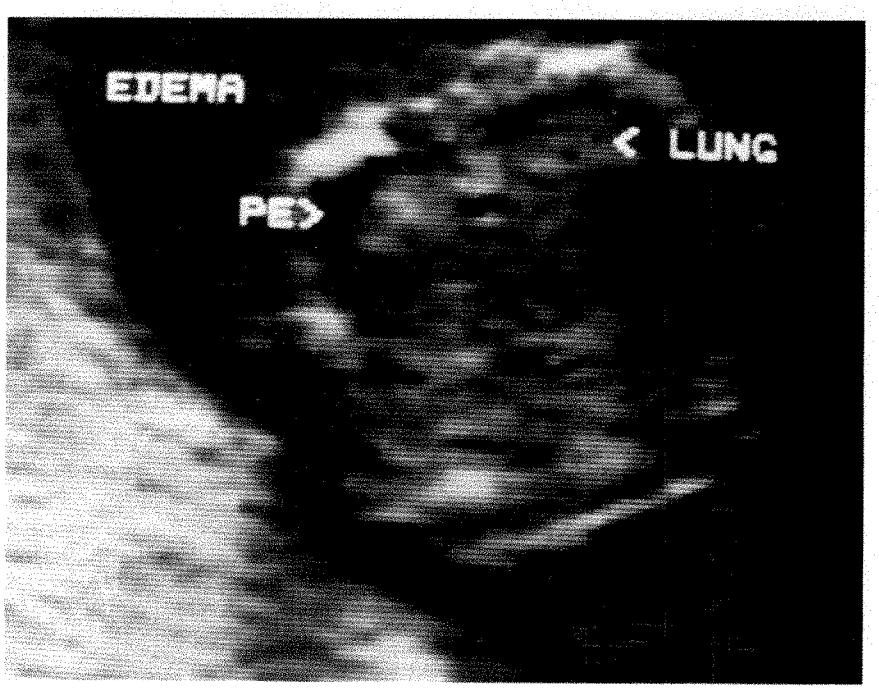

Fig. 10. Transverse ultrasonographic scan through 13-week embryo with posterior cystic hygromas and hydrops. Pleural effusions *(PE)* are shown.

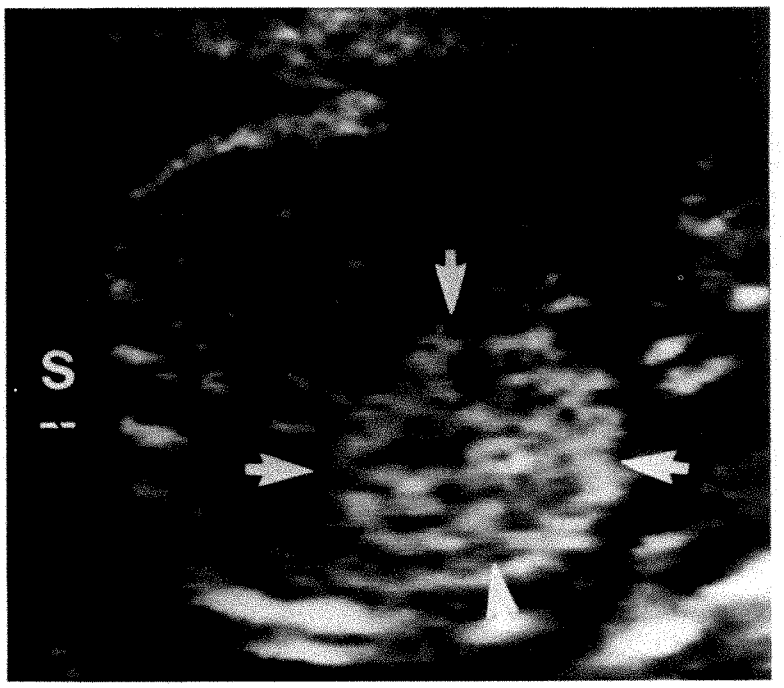

Fig. 12. Transverse scan in normal 12-week embryo with prominent bowel *(arrows)*. Spine *(S)* is shown.

trates some limitations. The incidence of a structural anomaly was surprisingly low. This could reflect a high number of low-risk patients that were examined. It is noteworthy that 22 of the 33 patients with an anomaly (66%) were at "high risk."

The mean gestational age at the time of diagnosis of the anomaly in this study was 11 weeks. This reflects limitations in the normal developmental sequence, delayed manifestation of disease (as in chamber dilatation in congenital heart disease), or late referrals.

We believe it is imperative to correlate pathologic and ultrasonographic findings especially during the early investigating period of first-trimester detection while establishing diagnostic criteria. Currently, few reports in the literature have such data available. Because routine suction curettage often makes pathologic confirmation difficult, prostaglandin abortion[16] or embryoscopy[4] can be used as an alternative.

Because of the limited experience with early antenatal screening of structural defects, serial scans should be performed before excluding an anomaly in a pregnancy at risk. We agree that experience with early ultrasonography and a thorough understanding of embryology must be gained before its application in first-trimester diagnosis.[22] The study design and the number of patients in the study do not allow a statement to be made about the sensitivity of the technique for the diagnosis of specific anomalies, but this and other preliminary data[7] suggest a future role for fetuses at risk. Prenatal diagnosis of structural anomalies will move into the first trimester.

Acromegaly first diagnosed in pregnancy: The role of bromocriptine therapy

A. S. Yap, MB, BS,[a] W. M. Clouston, MB, BS,[a] R. H. Mortimer, MB, BS,[a] and R. F. Drake, MB, BS[b]

Herston, Brisbane, Australia

We report a case of acromegaly diagnosed in the second trimester of pregnancy. Bromocriptine (7.5 mg per day) corrected visual field defects and suppressed prolactin secretion but did not reduce fasting growth hormone levels. We propose that suppression of physiologic lactotroph hyperplasia by bromocriptine may permit noninvasive management of pituitary adenomas during pregnancy. (Am J Obstet Gynecol 1990;163:477-8.)

Key words: Acromegaly, pregnancy, bromocriptine

Pregnancy in a woman with untreated acromegaly is very rare and to our knowledge has been adequately documented only once previously.[1] We report a woman whose acromegaly, complicated by optic chiasmal compression, was first recognized in pregnancy.

Case report

A gravida 2, para 1 woman aged 32 years was first seen at 18 weeks' gestation. Her first pregnancy 7 years previously was uneventful. Subsequently she had become hypertensive, had noticed increasing shoe size and abnormal sweating, and carpal tunnel compression developed that required surgery. Menses were irregular for 3 years before conception. From 16 weeks' gestation she experienced intermittent episodes of blurred vision. She had a coarse face, prognathism, and sausage fingers. Visual fields were normal by perimetry.

The pituitary fossa was not enlarged but the floor and posterior clinoids were eroded. Fasting growth hormone (GH) levels were high (37 mU/L; normal range, <10 mU/L) and failed to suppress with administration of glucose (peak GH was 44 mU/L), consistent with a diagnosis of acromegaly. The glucose tolerance test results showed diabetes. Prolactin levels were appropriate for her stage of pregnancy, and thyroid and adrenal function were normal.

Visual symptoms continued and minor abnormalities of red fields appeared on perimetry. Examination of visual-evoked responses showed prolonged central field latencies. An intrasellar tumor was shown by computerized tomography. Although no suprasellar extension was seen, concern about optic nerve compression prompted administration of bromocriptine in doses that were increased to 7.5 mg/day. Visual symptoms and field abnormalities resolved within 2 weeks. Prolactin levels were suppressed by bromocriptine without significant changes in GH levels (Fig. 1). A normal infant was delivered by cesarean section at 39 weeks' gestation. Bromocriptine was continued for 2 weeks postpartum to suppress lactation. Despite this there was an immediate postpartum increase in fasting GH levels and a significant reduction in prolactin levels.

Results of a repeat glucose tolerance test at 7 weeks postpartum were nondiabetic. Basal GH (108 mU/L) and peak GH (186 mU/L) levels were higher than those in pregnancy and basal prolactin levels (11 pmol/L) were normal. An intrasellar maroadenoma was confirmed by a second computerized tomography scan and an acidophil tumor resected transsphenoidally. The pituitary fossa was subsequently irradiated.

On follow-up, clinical signs of acromegaly and menstrual irregularity persisted but excessive sweating resolved. Serial glucose tolerance tests showed progressive decreases in GH levels.

Comment

Diagnosis of acromegaly requires demonstration of abnormal GH secretion, usually by elevated fasting levels and failure to suppress (or a paradoxical rise) with glucose administration. Earlier reports of acromegaly occurring in pregnancy have usually failed to provide such documentation or have been confounded by prior treatment. GH is less responsive to stimulation in normal pregnancy[2] and this dampened response, which was apparent in our patient but not in that previously reported,[1] may complicate the diagnosis of acromegaly. Although insulin-like growth factor 1 levels are raised in acromegaly and correlate better with disease activity than do GH measurements, the normal rise in insulin-like growth factor 1 levels

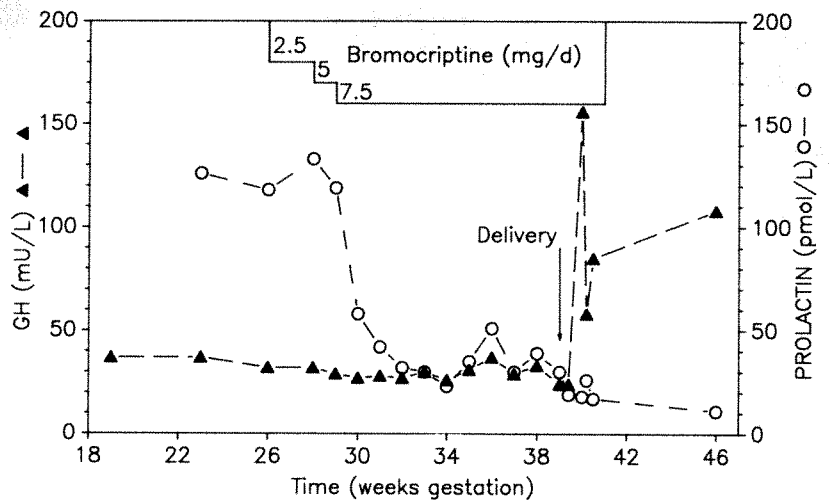

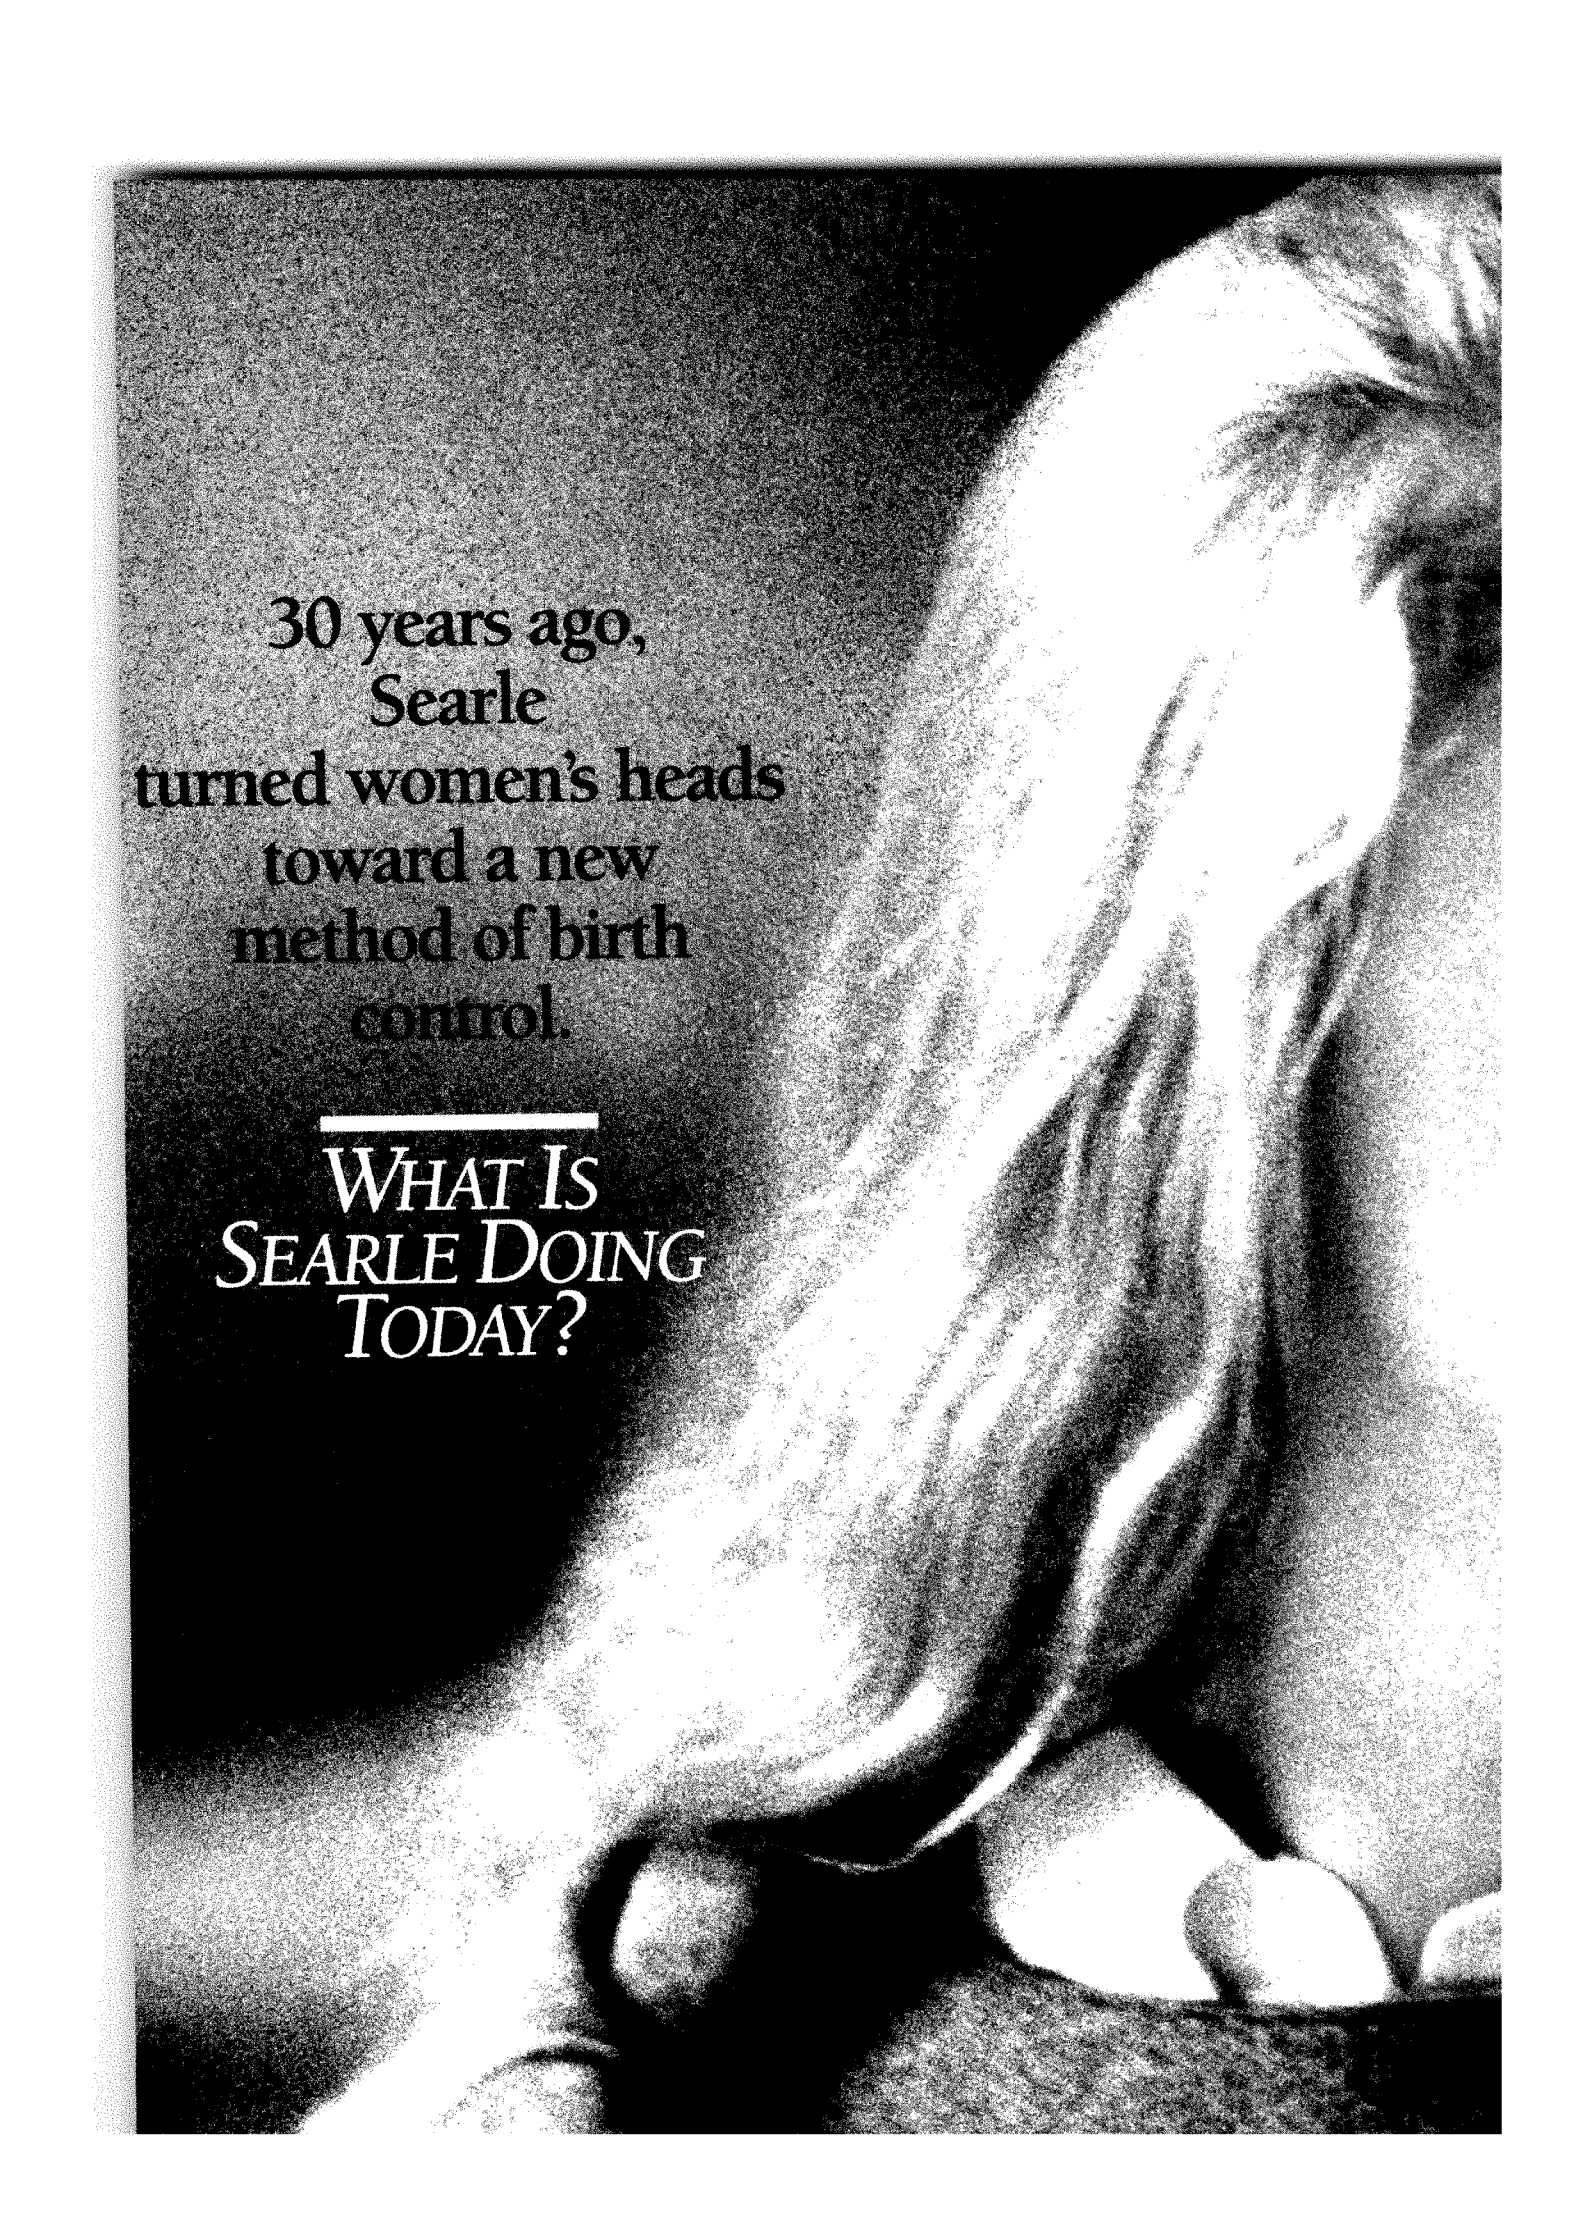

Fig. 1. Effect of bromocriptine on serial fasting growth hormone and prolactin levels during pregnancy and in early postpartum period. Fasting growth hormone normal range is <10 mU/L.

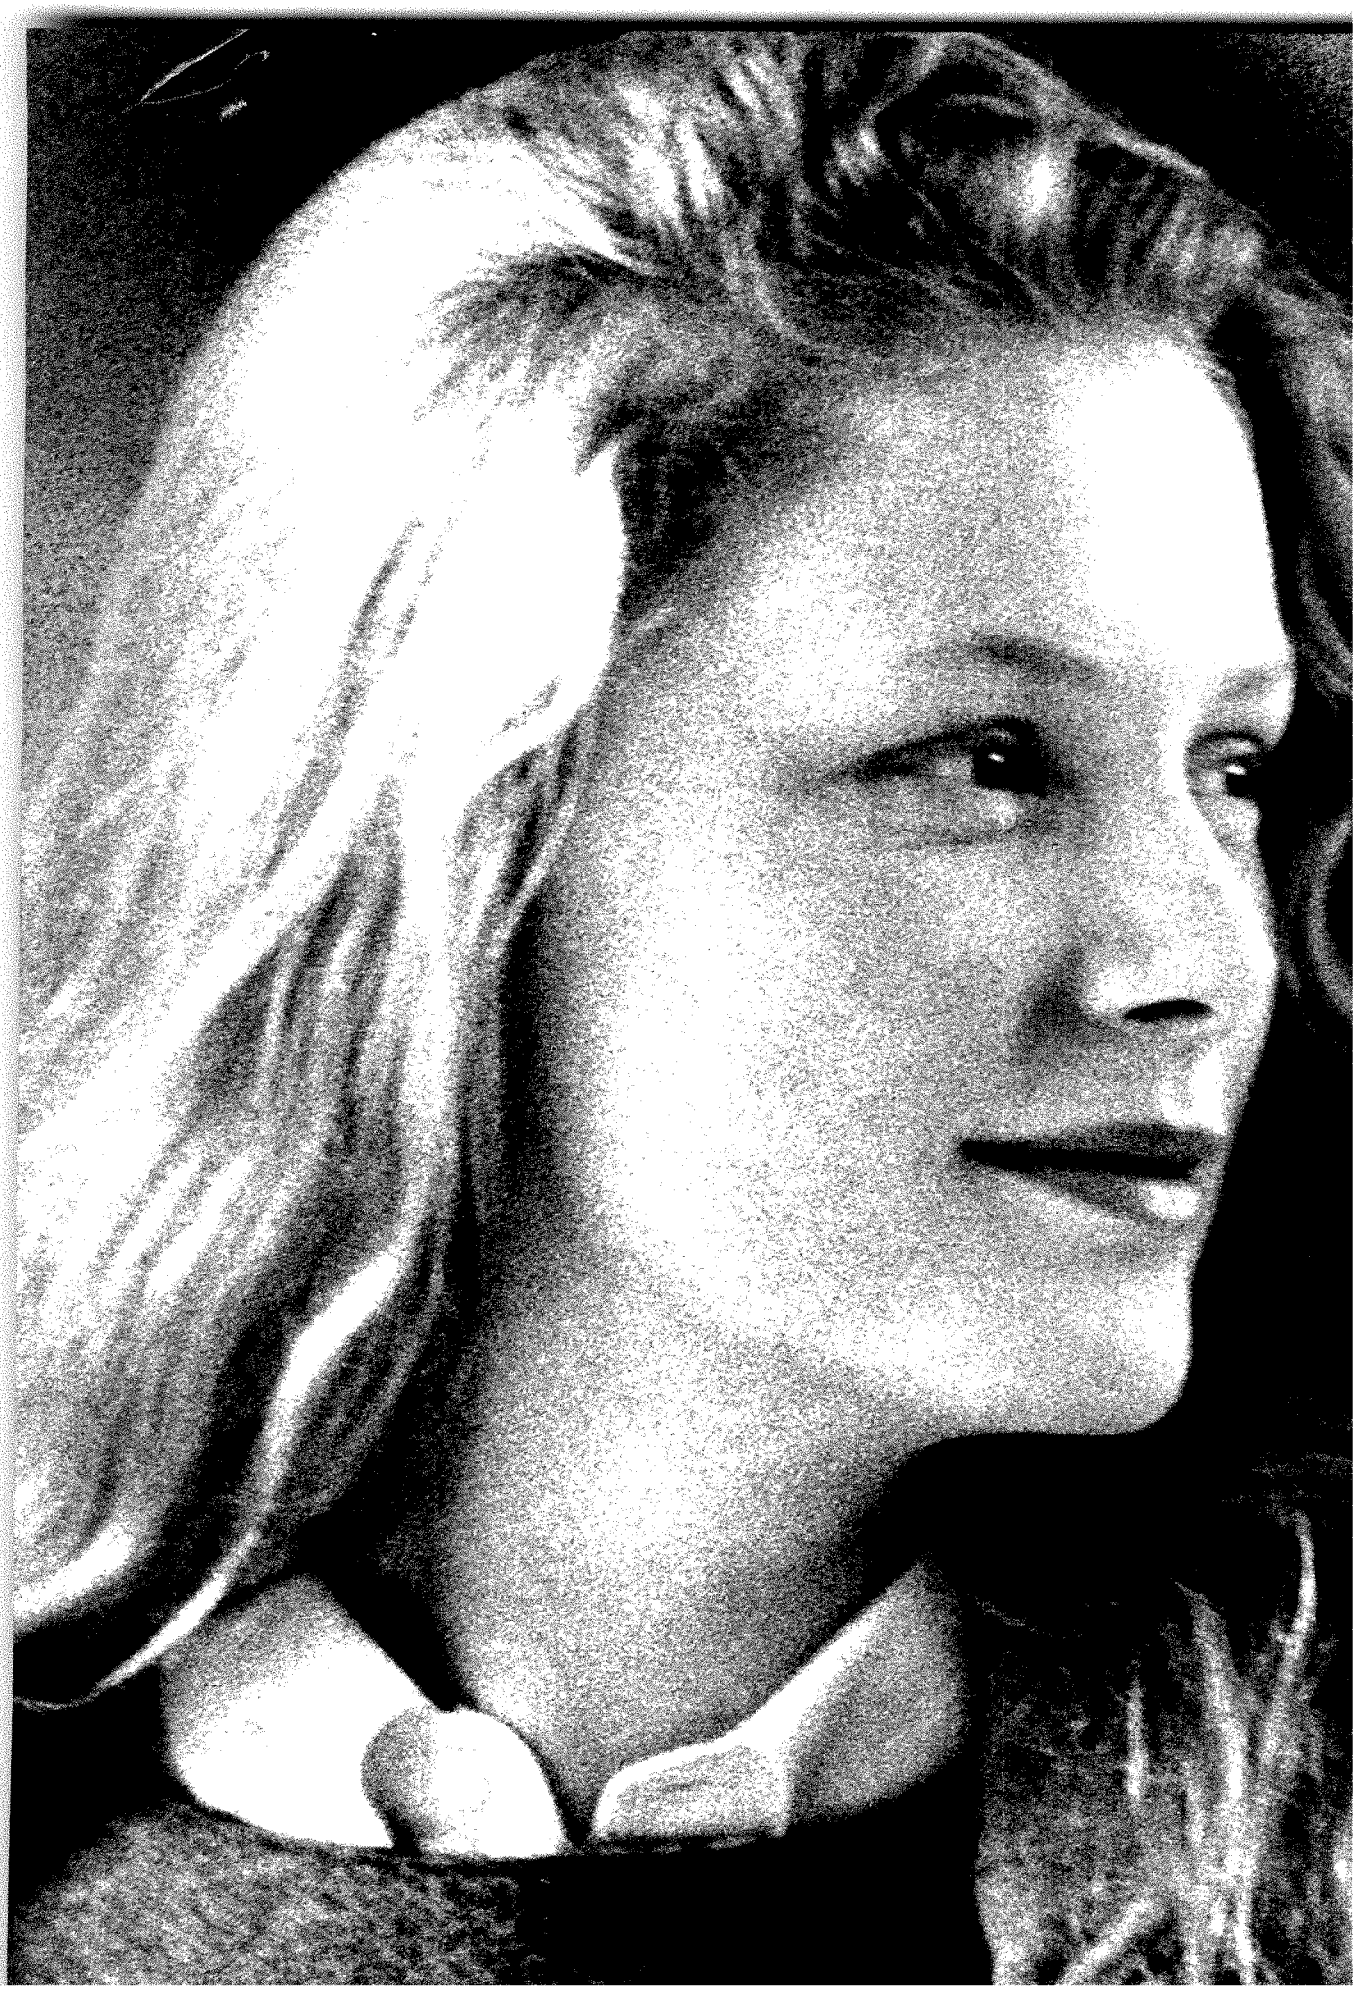

seen in pregnancy reduces the diagnostic utility of this test.

Tumor growth and compression of adjacent structures is a major potential complication of a pituitary macroadenoma in pregnancy. Our patient had evidence of optic nerve compromise but the suppression of normal pregnancy levels of prolactin by bromocriptine without associated changes in GH level suggests that resolution of visual field abnormalities resulted from suppression of physiologic hypertrophy of normal pituitary tissue rather than by tumor shrinkage per se.

WHAT IS
SEARLE DOING
TODAY?

MAKING A GREAT CASE FOR DEMULEN® 1/35

- New cosmetic case design—opens with the lightest touch
- Familiar interior display—no period of adjustment for current users
- Slim and lightweight—slips into pocket, purse, or wallet
- Helps her to remember—shows, at a glance, the last day a tablet was taken

THE CASE FOR PRESCRIBING DEMULEN 1/35

- Low-dose formulation
- Minimal lipid impact
- Low incidence of some common androgenic side effects, such as acne, oily skin, and hirsutism
- Unique progestogen: ethynodiol diacetate
- No generic substitute available
- Covered by the Patient Promise® program

  If you prescribe Demulen 1/35, or any other Searle product, and do not achieve the desired therapeutic benefits, at any time, Searle will refund 100% of your patient's out-of-pocket cost for her most recent prescription for that product, *a full refund directly to your patient.*

DEMULEN® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Also available in the new Compack®
DEMULEN® 1/50 (ethynodiol diacetate 1 mg, ethinyl estradiol 50 mcg)

Please see adjoining page for a brief summary of prescribing information.

The physician should become familiar with the prescribing information (labeling) for this product, which discusses reported risks, such as thromboembolic disorders (including strokes and heart attacks), risk of estrogen dose, and hepatic lesions, as well as the need to monitor patients for early symptoms of any diseases or medical conditions, so use can be discontinued when appropriate.
A brief summary of the prescribing information accompanies this advertisement.

DEMULEN® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

BRIEF SUMMARY

Demulen® 1/35: Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients. **Demulen® 1/50:** Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients.

Indication and usage: For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk:* Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen.

Contraindications: Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products.

Warnings:

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. *Thromboembolic disorders and other vascular problems:* Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders:* In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction:* Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking is a major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers		10.2	2.6		62.0	15.9
	≥15 cigarettes daily	13.0	5.1		78.7	31.3
	<15 cigarettes daily	4.7	0.9		28.6	5.7
Nonsmokers		1.8	1.2		10.7	7.4
Smokers and nonsmokers		5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. Latter group also had more venous TE. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. Decreased HDL, which relates to increased myocardial ischemia, occurs with high progestational activity. Consider amount of both steroids in choosing OC. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases:* A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low.	Age:	<30	30-39	≥40
Heavy smokers (≥15/day)		C	B	A
Light smokers (<15/day)		D	C	B
Nonsmokers, no predispositions		D	C,D	C
Nonsmokers, with predispositions		C	C,B	B,A

Be alert to earliest manifestations of TE disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. RCGP reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. Varicose veins have little effect on development of deep vein thrombosis. **2.** *Ocular lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma:* Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. Estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased end cancer with combination or progestogen-only OCs. Studies show no increased breast cancer with OCs or estrogens. H greater risk was noted in OC users with benign breast disease or long-term (2-4 years) use. One study found greate breast cancer with >4 years OC use prior to first full-term pregnancy. Risk of breast cancer with menopausal estrog and further increased with duration of follow-up. OCs or estrogen were related to breast cancer in connection with o factors and in various subgroups. Decrease in benign breast tumors in OC users is well known. Some studies su increased risk of cervical dysplasia, CIN, erosion, and carcinoma in long-term users. Cervical microglandular hyperpl been reported. In summary, there is no consistent evidence from human studies of increased cancer risk with OC surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consider nonfu causes and take diagnostic measures to rule out malignancy. Carefully monitor users with strong family history c cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical d **4.** *Hepatic adenomas, etc,* have been associated with OCs. In 1 study OC formulations with high "hormonal potenc associated with higher risk, as was age over 30. Though benign, these lesions may rupture and cause fatal hemope in short- or long-term users. Two studies related risk to duration of use, being much greater after ≥4 years. Long- users have an estimated adenoma incidence of 3-4/year/100,000. Consider such lesions in users with abdomi tenderness, mass, or shock. About 25% present with abdominal masses, up to half with acute hemoperitoneum. R and lab studies may not be helpful; liver scans may show local defect. Hepatic arteriography or CAT may b Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. Bile duct cancer may occur with **5.** *Use in or immediately preceding pregnancy, birth defects, malignancy in offspring:* Estrogens or progestogens dur pregnancy may seriously damage offspring. Females exposed in utero to DES and other nonsteroidal estrogens m increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monitor such patients carefully. F 90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. DES- daughters have more unfavorable pregnancy outcomes. Males so exposed may develop urogenital and sperm defect estrogens may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, eg, VAC vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects. There appears preferential expression by male was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal wi pregnancy tests, or treatment for threatened abortion). Some exposures were very short; being only a few days. Cardio defects in children exposed to female hormones, including OCs, during early pregnancy occurred in 18.2/1,000 compared to 7.8 for those unexposed (P<.05). Female hormone exposure in utero was associated with testicular anc cancer. More twinning was reported in conceptions shortly after OC discontinuance. Female sex hormones were threatened or habitual abortion, but there is considerable evidence estrogens are ineffective and no evidence progr are effective. Triploidy and possibly other polyploidy may be increased in abortuses from women becoming pregna post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion is increased soon after OCs. Increased chromosome aberrations have been reported. Safety of OCs in pregnancy has not been demonstrat out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods are rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and OCs. If pregnancy is confirmed, stop OC and apprise patient of potential fetal risks and discuss continuation of pre Users discontinuing for pregnancy should use alternative contraception for 3 months before attempting to conceive this is not based on precise information. Do not use progestogen-only or progestogen-estrogen drugs as pregnanc **6.** *Gallbladder disease* risk, surgically confirmed, appeared after 2 years' use and doubled after 4-5 years in 1 appeared in 6-12 months' use in another. Bile duct cancer has been reported. **7.** *Carbohydrate and lipid metabolism:* De glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Triglyc total phospholipids, and lipoproteins may increase. **8.** *Elevated blood pressure* (BP) occurs in some users in a few and degree may relate to progestogen dose. Hypertension prevalence in users is not higher in the first year, but ri with longer exposure; in the 5th year it is 2½–3 times the first year. Age is strongly correlated with hypertension i Those with history of elevated BP (hypertension), preexisting renal disease, history of toxemia or elevated BP in pre familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during m cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Even though elevated BP in "normal" range, do not ignore implications. Follow closely, particularly those with other risk factors for cardio disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache:* Onset or exacerbation of mig development of headache of a new pattern that is recurrent, persistent, or severe requires stopping OCs and evaluatin **10.** *Bleeding irregularities:* Breakthrough bleeding (BTB), spotting, and amenorrhea are frequent reasons for discontir BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleed out pregnancy or malignancy. If pathology is excluded, time or change to another product may suffice. Change to a estrogen OC only when necessary as this may increase thromboembolic risk. Those with history of oligomeno secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinuing with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolong occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors has been as with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in with postpill amenorrhea when galactorrhea was present. **11.** *Ectopics:* In failures with combination OCs, the ratio of to intrauterine pregnancies is no higher than in nonusers. **12.** *Breast feeding:* OCs may decrease quantity and quality A small fraction of OC steroids appears in milk. Effects if any on child are unknown. If feasible defer OCs until after **13.** *Infertility* may occur after discontinuing OCs. While impairment diminishes with time, there is still an appreciable di in nulliparas aged 25-29 after 30 months; difference is negligible after 48 months. In nullips aged 30-34 impairment to 72 months and is more severe for 2-year users. In paras aged 25-34, difference is negligible after 30 months. **Pre** Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen, and pel BP, Pap, and lab tests. Preexisting uterine leiomyomata may enlarge. Mental depression may occur; with positive observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monitor in convulsive disorders, migraine, asthma, or cardiac, hepatic, or renal dysfunction. History of jaundice in pregnancy ir risk of recurrence on OCs; observe carefully and discontinue if it occurs. Cholestatic jaundice occurred after troleandomycin use. OC/cyclosporine combination may be hepatotoxic. Steroids may be poorly metabolized in liver dys and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megal anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pat of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after s for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; in prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; in thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T_4); decreased T_3 uptake, unalte T_4, decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, trigl phospholipid, reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonged on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response not established. OCs may mask climacteric. Cervical chlamydial and gonorrheal prevalence is increased; do not assume OC protects against chlamyc HIV seropositivity was associated with OC use. *Information for patients.* See patient labeling. *Drug interactions.* OC effect may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomycin, penicillin V, tetracycline, chloramp sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine, primidone, phenylbutazone, ana tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants, anticonvulsants, tranquilizers, antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, acetami **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thrombo and thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; c thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrome; adenomas and other hepatic lesions, with or without intra-abdominal bleeding; liver cancer, congenital abnormalities evidence of association between the following and OCs, though confirmatory studies have not been done: me thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The following are believed drug related: vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during a use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlar secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, ch jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or refu premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, pare nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multi nodosum, hemorrhagic eruption, herpes gestationis, hidradenitis suppurativa, hemolytic uremia, malignant hyper impaired renal function, acute renal failure, sometimes irreversible, itching, vaginitis, porphyria, PVCs, abnorm pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus erythem rheumatoid arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant me endometrial, cervical, breast, and bile duct carcinoma. **Acute overdosage:** Serious ill effects have not been report large acute doses of OCs in young children. Nausea and withdrawal bleeding might occur. **Important note: Co prescribing information should be consulted prior to use and is available on request.**

DO YOU KNOW WHO YOUR PROBLEM PATIENTS ARE?

MONDAY, JULY 23, 1990:

Tammy McDonald is 18 weeks pregnant and has an elevated AFP. She missed her perinatal exam Friday. ***Will your office call her this morning?***

Sheena Brandt's EDD was July 16th. You haven't heard from her. ***Will your staff follow up today?***

Brenda Martin's chart was in Dr. Jessup's office. He saw her for her last exam while you were in Delivery. ***Does anyone know where her chart is now?***

You accidentally charted the wrong EDD for Nicole Arevalo. ***Will you immediately be alerted to the error?***

If your office isn't managing high-risk situations, then you're practicing high-risk medicine. Pro-active patient tracking procedures are the only sure way to protect both your patient... and your practice.

With **The OB Manager,** you can track patient progress before negative consequences result and alert your staff to critical follow through procedures. No more lost memos. No loose details. Just common sense software that retains crucial patient data and directs your staff with daily online instructions that keep you in charge.

The OB Manager's pro-active patient care program keeps you on top of your practice.

With a full range of instant reports from patient listings by provider, status, and risk factors to past due dates and abnormal test dates, **The OB Manager provides quality assurance and protection for your future.**

THE PERMANENTE MEDICAL GROUP

NORTHERN CALIFORNIA

The Permanente Medical Group, the largest multispecialty group practice in the U.S., is undergoing explosive growth in its Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley. Our rapid increase in membership has created practice opportunities throughout the region for additional BC/BE Obstetricians and Gynecologists.

Our physician-managed group is part of the comprehensive Kaiser Permanente Medical Care Program. As a TPMG physician, you have access to the latest medical technology and resources, the support of colleagues in all subspecialties — and the opportunity to provide excellent health care without the burdens of managing a practice.

Join us in one of these facilities:

QUALITY

STABILITY

LEADERSHIP

GROWTH

SUPPORT

REWARDS

Richmond — Small, congenial clinic setting staffed by five physicians and five nurse practitioners with ready consultation for other services, including perinatology. Practice general OB/GYN, high-risk obstetrics and infertility. Expertise in colposcopy, laparoscopy, hysteroscopy and laser welcome. Resident teaching opportunities exist. Staff call at Kaiser Hospital in Oakland, shared with resident staff.

Oakland — Twenty physicians, 12 residents offer services in oncology, infertility, maternal-fetal medicine and a large ICN.

Redwood City — Specializes in family-centered maternity care; offers modern LDR rooms and full range of gynecological surgery. With ten physicians, 24-hour call is required three times each month. Beautiful Peninsula location, near San Francisco and the Pacific Ocean.

Stockton — Small four physician department in a new clinic building with new equipment, including laser. Stockton's lifestyle is affordable and attractive, offering recreational activities such as boating on the inland waterways. Centrally located, with mountains to the east and San Francisco Bay Area to the west.

Roseville — Eight physicians and two nurse practitioners in clinic setting. Patients are hospitalized for delivery and surgery in Sacramento where physicians take call for L&D and emergency about 5 times each month.

San Francisco — Full range of services including large high-risk, tertiary care OB service. Eighteen physicians, including GYN Oncologist. Residency program. Clinical research and academic teaching appointments available.

Sacramento — Growing metropolitan area between San Francisco Bay Area and Sierra Nevada mountains. Up-to-date facility with active staff of 14 and excellent residency program affiliated with the University of California at Davis. Flexible call averaging five shifts per month covers L&D, emergency room and inpatient services.

Pleasanton — Staffed by four physicians and three nurse practitioners, clinic provides general OB/GYN services, non-stress tests, ultrasound and cystoscopy. Consultant support, including a Perinatologist, readily available. Share call with staff of Walnut Creek Medical Center. Affiliated with the University of California at San Francisco as clinical instructors.

Fresno — Ground-floor opportunities in growing area for clinically-oriented individuals. Provide general OB/GYN; special interests encouraged. Planning new $26 million outpatient facility to accompany current medical office building. On call every fourth night and weekend. Local residency program at Valley Medical Center affiliated with the University of California at San Francisco. Teaching positions possible.

South San Francisco — Full service except L&D. Nine physicians, six nurse practitioners. On San Francisco Peninsula, 15 minutes from downtown.

KAISER PERMANENTE
Good People. Good Medicine.

TPMG offers many benefits: scheduled time off with cross-coverage provided by your colleagues, continuing education, malpractice insurance, a substantial retirement program and special arrangements for physicians transferring from established practice. Epithelial cells from normal human endometrium express a tumor-associated glycoprotein (TAG-72) epitope in vitro

Kevin G. Osteen, PhD,[a, b] Ted L. Anderson, PhD,[a, b] Joel T. Hargrove, MD,[a] George A. Hill, MD,[a] and Fred Gorstein, MD[b]

Nashville, Tennessee

Monoclonal antibody B72.3 identifies a tumor-associated glycoprotein (TAG-72) epitope derived from a human breast carcinoma metastasis. Recently, expression of this epitope was noted in normal endometrium during the secretory, but not proliferative, menstrual interval. In light of known hormonal control of normal endometrial growth and differentiation, we investigated in vitro expression of TAG-72 epitope in purified endometrial epithelium cultured under serum-free conditions on Matrigel biomatrix. Cells from secretory endometrium exhibited homogeneous tumor-associated glycoprotein 72 epitope expression. Unexpectedly, epithelium from the proliferative interval developed expression after 5 to 6 days of culture. Epithelial cells from both intervals maintained expression over 12 days of culture without exogenous estradiol and progesterone. Spontaneous, uniform expression of tumor-associated glycoprotein 72 epitope by normal endometrial epithelial cells in vitro is in marked contrast to the cyclic, heterogeneous expression observed in vivo. Such expression also differs from published in vitro observations of cancer cell lines that express this epitope. (Am J Obstet Gynecol 1990;163:479-84.)

Key words: Endometrium, epithelium, matrix, tissue culture, differentiation, tumor epitope

Monoclonal antibody B72.3 is directed against a high molecular weight membrane-associated determinant extracted from a breast tumor metastasis.[1] Shown to be immunoreactive with carcinomas of the breast, ovary, colon, and uterus,[2-5] this antibody was originally reported to be nonreactive with normal adult epithelium from a variety of tissues.[3, 4] Subsequently, however, monoclonal antibody B72.3 was reported to recognize normal human endometrial epithelium, but only during the secretory menstrual interval.[5]

The antigen recognized by monoclonal antibody B72.3 has been designated tumor-associated glycoprotein 72 (TAG-72), which has not been well characterized. A partial purification of TAG-72 from a xenograph of a colon cancer cell line (LS-174T) in athymic mice found the epitope to be a neuraminidase-sensitive mucin-like molecule.[6] Recent studies indicate that monoclonal antibody B72.3 reacts with the core region of O-linked sialosyl-2→6α-N-acetylgalactosaminyl (sialosyl-Tn) epitope.[7]

Although the degree of TAG-72 expression in tumor cell xenografts approximates that observed in tumor masses in situ, this level of expression is not exhibited by tissue cultures of similar tumors.[8] Maintenance of TAG-72 expression by LS-174T cells in vitro is poor, and appears to depend on the three-dimensional architecture of cells in the culture system; LS-174T cells grown in agar gels expressed a 10-fold higher level of TAG-72 compared with cells grown on plastic.[8]

Our attention has focused on the stage-specific recognition of normal human endometrium by monoclonal antibody B72.3, which promises to be a useful differentiation marker in this tissue and may provide unique opportunities to examine the regulation of TAG-72 epitope expression. To this end, methods have been developed to isolate, with high purity and viability, glandular epithelium from normal human endometrium.[9] When cultured appropriately on biomatrix, these cells were found to establish and maintain an in vivo—like architecture and polarity.[10] In the present study we examined the pattern of B72.3-reactive epitope expression in vitro by normal human endometrial epithelium obtained during proliferative versus secretory intervals of the menstrual cycle, and we compared such expression with that observed in vivo.

Material and methods

Sources of tissue. Endometrial biopsy samples were obtained from normally cycling women for indications

not associated with uterine dysfunction during the mid-proliferative (cycle days 5 to 10; $n = 7$) and mid-to-late secretory (cycle days 21 to 26; $n = 9$) intervals. All samples were obtained and used with prior approval of the Vanderbilt University Committee for the Protection of Human Subjects. Specimens were collected in a 1:1 mixture of phenol red-free Dulbecco's modified Eagle's medium and Ham's nutrient mixture F-12 with 15 mol/L hepes, antibiotics, and 10% charcoal-stripped fetal bovine serum (DME/F-12/FBS) for transport to the laboratory. A portion of each sample was placed in 4% buffered formalin for routine histologic evaluation and for immunohistochemical studies as described later.

Purification of epithelial cells. Endometrial biopsy tissue was dissected into small pieces (1 to 2 mm^3) and washed by centrifugation (400 *g*) in fresh medium to remove debris and most blood cells. Epithelial cell isolation was accomplished by a procedure involving selective enzymatic digestion, filtration, unit gravity sedimentation, and selective plating, as previously described.[9] Briefly, tissues were incubated with DME/F-12 containing 0.5% collagenase, 0.02% deoxyribonuclease, and 2% chicken serum for 1 hour at 37° C in a shaking water bath. Cell clumps were dispersed by aspiration through a siliconized Pasteur pipette after 30 minutes of digestion.

After initial tissue digestion, most stromal cells were separated from large epithelial clumps by filtration through two nylon membrane filters (105 and 88 μm, respectively). Retained epithelial clumps were washed in Hank's balanced salt solution (pH 7.4) by centrifugation (400 *g*) before further enzymatic digestion in Hank's balanced salt solution containing 0.5% collagenase, 0.1% hyaluronidase, 0.1% pronase, 0.02% deoxyribonuclease, and 2% chicken serum. Subsequent to the second enzymatic digestion clumps of epithelial cells were collected on an 88 μm nylon mesh filter (allowing contaminating stromal cells to pass), washed twice, and resuspended in 2 ml DME/F-12/FBS. This suspension was layered over 10 ml of DME/F-12/FBS in a 15 ml conical tube for a 30-minute unit gravity sedimentation at 37° C. This step was repeated with only the bottom 2 ml of cells from the first sedimentation.

Final purification of epithelial cells was achieved by allowing rapid selective adherence of the few remaining stromal cells to 25 cm^2 tissue culture flasks. Epithelial clumps were suspended in DME/F-12/FBS and plated for 30 minutes at 37° C in a humidified environment with 5% carbon dioxide. The nonattached epithelial cells were collected and the procedure was repeated once. Epithelial cell viability was ascertained in a 0.04% solution of trypan blue in phosphate-buffered saline solution (pH 7.2), and an estimate of cell numbers within each cell preparation was determined with a hemocytometer.

Epithelial cell cultures. For routine assessment of culture purity, epithelial cells were cultured for 2 to 3 days as a monolayer on Thermanox tissue culture disks (Miles Laboratories, Naperville, Ill.) placed in four-well culture plates. These cells were evaluated morphologically and with an immunohistochemical probe for the epithelial cell-specific intermediate filament, cytokeratin, as previously described.[9] Otherwise, purified epithelial cells were cultured in Millicell-CM tissue culture plate inserts (Millipore Products Division, Bedford, Mass.) coated with a layer of Matrigel biomatrix (Collaborative Research, Boston, Mass.). Between 1 to 5×10^5 cells/insert were seeded and allowed to attach in DME/F-12/FBS for 48 to 72 hours. Subsequently, cultures were maintained up to 12 days in serum-free DME/F-12 medium supplemented with insulin, transferrin, selenium, bovine serum albumin, and linoleic acid (ITS$^+$; Collaborative Research, Boston). On termination, inserts containing cells cultured on biomatrix were washed in ice-cold phosphate-buffered saline solution and fixed in 4% buffered formalin. Subsequently, the support membranes with attached epithelial cells were carefully removed from inserts with a scalpel and embedded in paraffin for localization of cellular TAG-72 epitope by monoclonal antibody B72.3 immunoreactivity.

Immunohistochemistry. The cytokeratin monoclonal antibody PKKI, directed against a 40 to 60 kd cytoskeletal fraction from pig kidney epithelial cells was purchased from Labsystems (Morton Grove, Ill.). Monoclonal antibody B72.3 used for this study was generated in the laboratory of Dr. Jeffrey Schlom (National Cancer Institute Section on Tumor Immunology, Bethesda, Md.).[1-5] Immunolocalizations of TAG-72 epitope or cytokeratin were accomplished with the avidin-biotin complex technique,[11] with streptavidin to lower background staining. As a negative control, an identical isotype antibody (monoclonal antibody MOPC-21; Litton Bionetics, Charleston, S.C.) was used under the same conditions.

Sections from paraffin-embedded biopsy specimens or cells grown on biomatrix were pretreated with heat-inactivated horse serum, washed in phosphate-buffered saline solution, and exposed to primary antibody (1:100 in phosphate-buffered saline solution containing 1% horse serum) for 1 hour at room temperature. Specimens then were washed and incubated with biotinylated secondary antibody (horse antimouse immunoglobulin G) for 1 hour. After further washing, tissues were exposed to streptavidin-biotin-peroxidase complex for 1 hour and reactivity was visualized with diaminobenzidine. All specimens were counterstained with Gill's hematoxylin and examined by light micros-

copy. Immunoreactivity was considered positive when a distinct, brown, granular diaminobenzidine precipitate was evident.

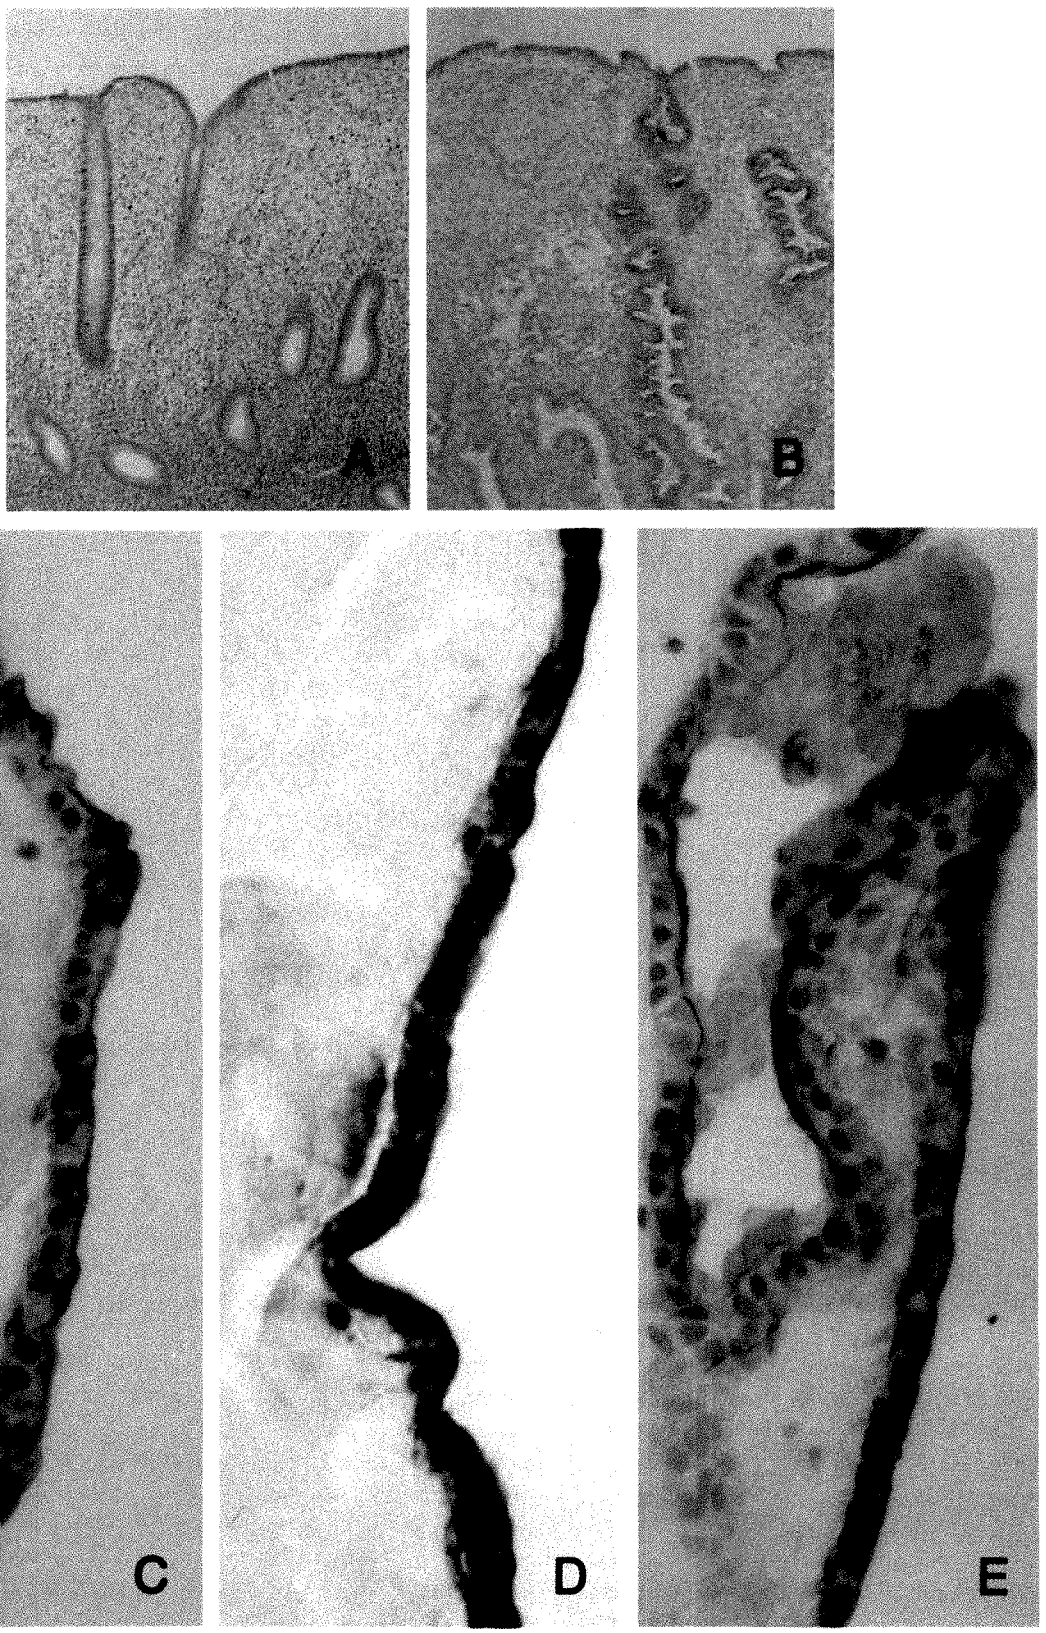
Results

Immunoreactivity of endometrial biopsy specimens to monoclonal antibody B72.3. No sample (n = 7) of intact endometrium obtained during the proliferative interval of the menstrual cycle intially showed monoclonal antibody B72.3 immunoreactivity in any region of the tissue (Fig. 1, *A*). Conversely, all (n = 9) biopsy specimens obtained during the secretory menstrual interval showed immunoreactivity to monoclonal antibody B72.3 in glandular epithelium and, to a lesser extent, luminal surface epithelial cells (Fig. 1, *B*). Considerable heterogeneity of TAG-72 epitope expression was noted between luminally situated glands (strongest reactivity) and basal glands (no reactivity). Furthermore, some cellular heterogeneity was observed among adjacent luminal glands such that the number of immunoreactive cells among the luminal glands ranged from approximately 10% to >30%. Immunoreactive material was often noted in the lumen of reactive glands.

Isolation and assessment of endometrial epithelium. The yield of purified epithelium from the portion of biopsy material available for study did not vary appreciably in relation to either patient age or menstrual interval and consistently ranged between 10 to 15 × 10^6 cells. Cell viability after purification procedures was routinely >90%. Thus a minimum of 10 culture replicates could be established from each biopsy sample. Epithelial cells cultured on Thermanox tissue culture disks assumed a flattened, whorled configuration after 3 to 4 days, and the purity of these cell populations was assessed by cytoplasmic immunoreactivity to anticytokeratin antibody. Consistent with previous observations,[9] contamination of epithelial cell preparations by stromal or endothelial cells was <5%.

Immunoreactivity of cultured epithelium to monoclonal antibody B72.3. A uniform monolayer of cuboidal cells was evident after 5 to 6 days of culture on biomatrix, in contrast to the flattened morphology of epithelial cells cultured on plastic. Cells cultured on biomatrix maintained a polar cellular architecture that is characteristic of in vivo epithelium. No overt differences in cellular morphology could be detected by phase microscopy between cells from biopsy specimens obtained during the proliferative versus the secretory menstrual interval.

After 4 to 6 days of serum-free culture on biomatrix, strong immunoreactivity with monoclonal antibody B72.3 was shown in cells obtained during the secretory interval (Fig. 1, *C*). Such immunoreactivity was maintained for up to 12 days, at which point cultures were terminated. Unexpectedly, a similar pattern of monoclonal antibody B72.3 immunoreactivity was observed in epithelial cells isolated from proliferative interval biopsy specimens by 8 days of serum-free culture on biomatrix (Fig. 1, *D*), which was also maintained until cultures were terminated.



Cells cultured on a thin layer of biomatrix generally appeared to form a continuous polar monolayer. However, near the edge of culture plate inserts where a meniscus effect produces a slightly thicker biomatrix bed, some epithelial cells appeared to organize into folded gland-like structures (Fig. 1, *E*). These "glands" were present in cultures of epithelial cells obtained during both proliferative and secretory intervals, and closely resembled in vivo glandular architecture. The apical surface of cells forming these structures was found to be highly immunoreactive to monoclonal antibody B72.3, and immunoreactive material was often present within the "lumen" as well.

Comment

Our observations of monoclonal antibody B72.3 immunoreactivity in glandular epithelium of normal secretory interval endometrium is consistent with those previously reported,[5] but the physiologic significance of TAG-72 epitope expression remains unknown. It also remains unclear whether such immunoreactivity reflects expression of the same molecule elaborated by tumor cells (TAG-72), or whether an identical or similar epitope is an integral component of an otherwise unrelated molecule.

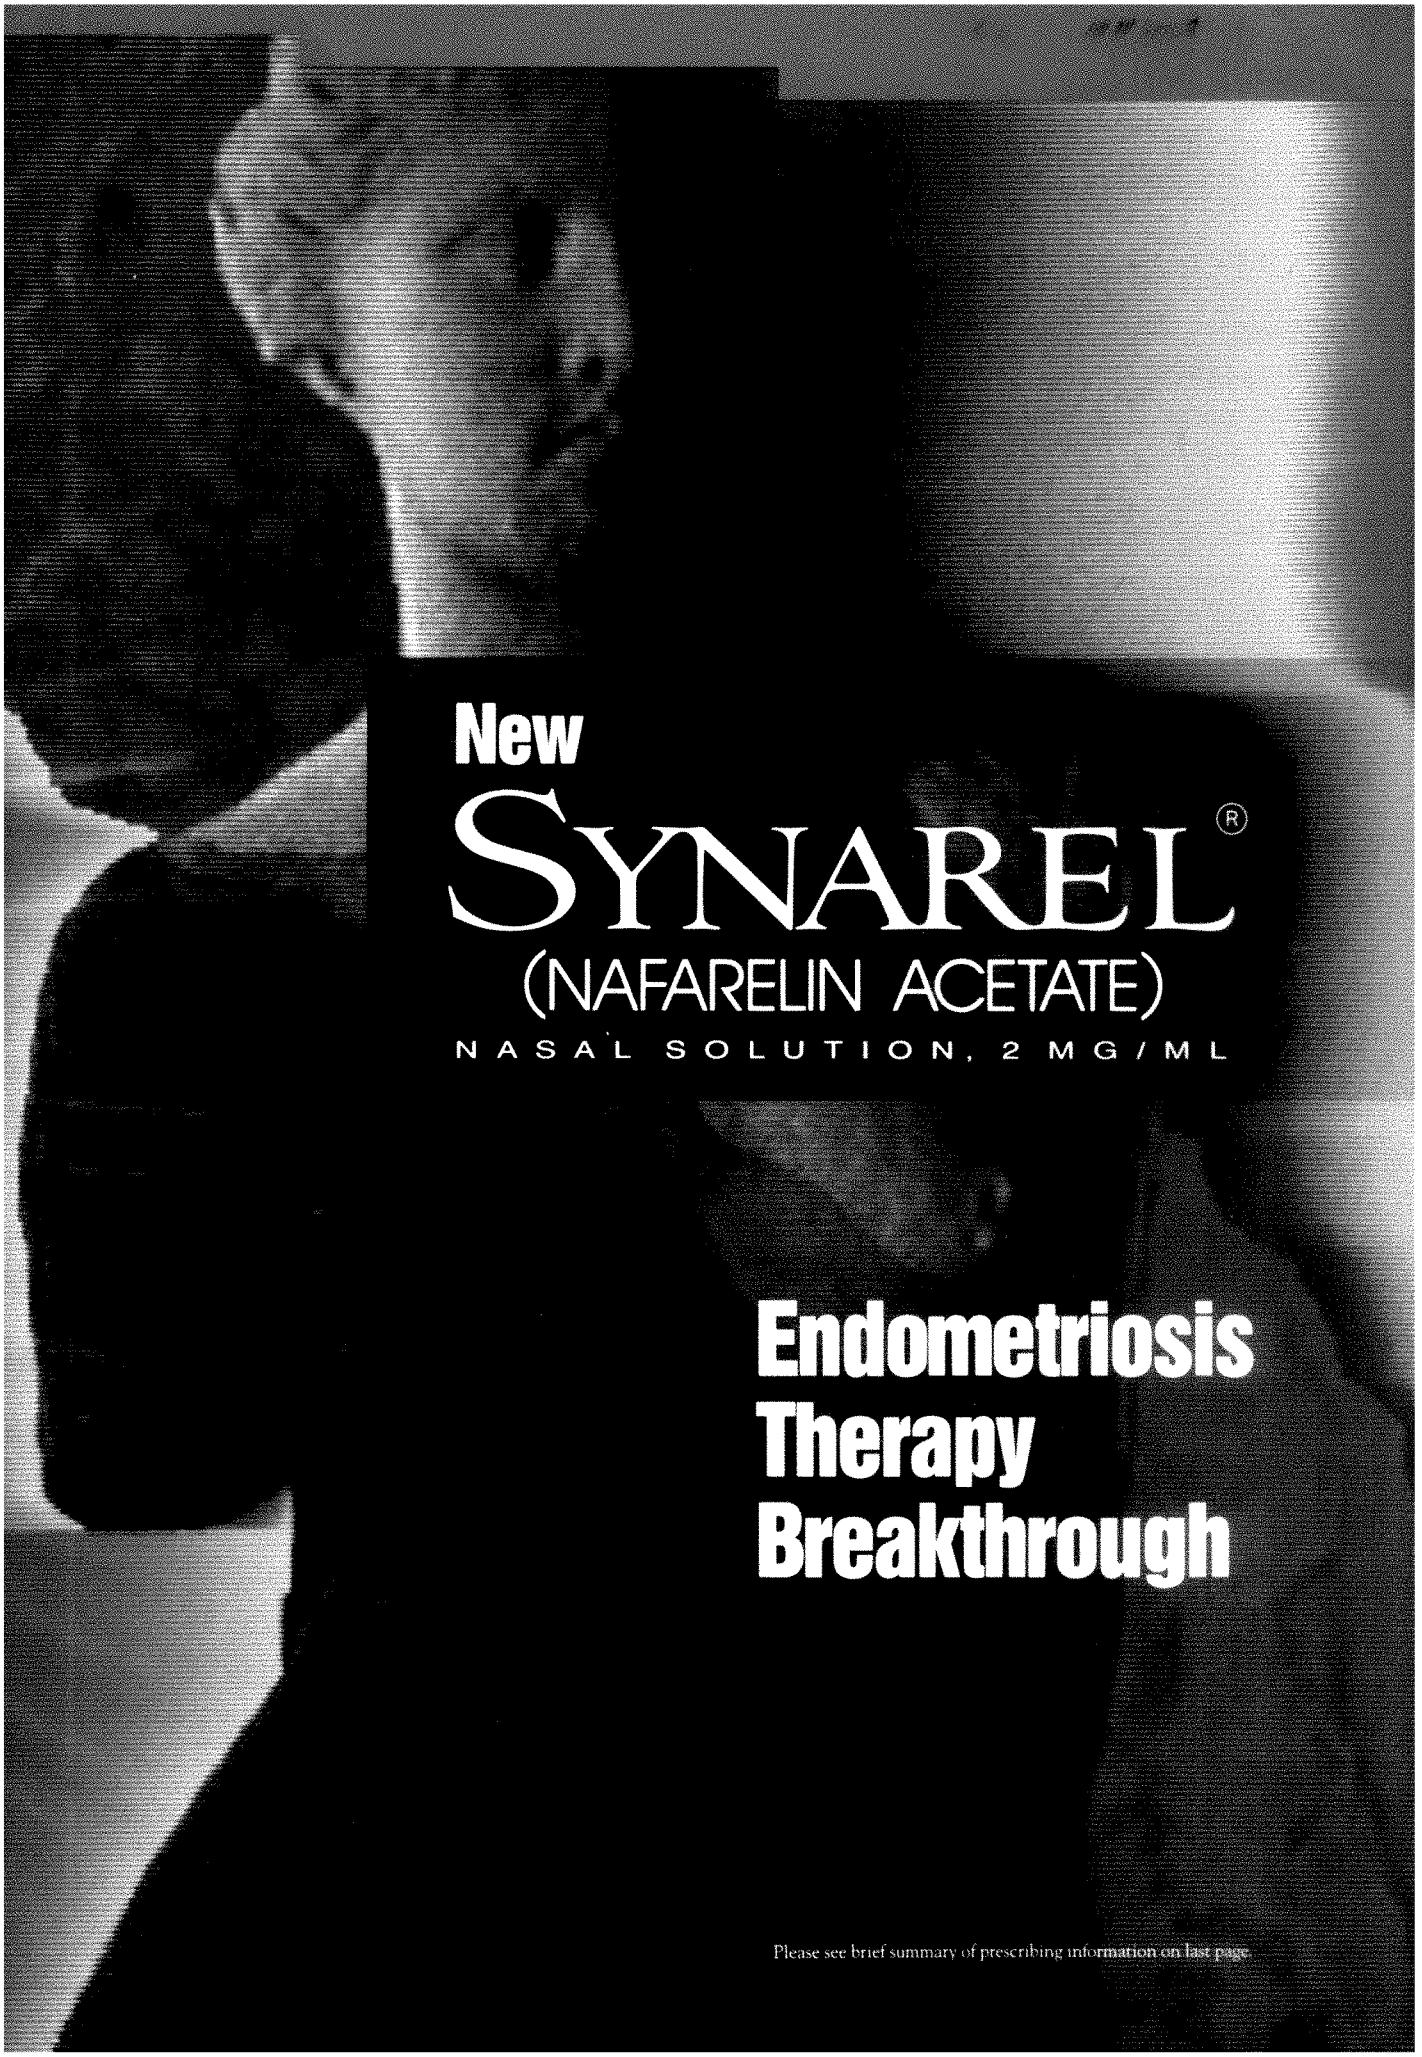
The possibility exists that monoclonal antibody B72.3 recognition of secretory endometrium may bear a coincidental relationship to the expression of this epitope in tumors. Monoclonal antibodies directed against specific epitopes have been shown to cross-react with other antigenic determinants with enough structural similarity to allow recognition,[12] and often with apparently unrelated antigens.[13] For example, monoclonal antibodies raised against insulin and growth hormone recognize tissues in which those genes are not expressed.[14] This unexpected multiple organ reactivity is a widely recognized phenomenon rarely observed with polyclonal antisera.

Recent research has emphasized the importance of polarity in cell functions such as endocytosis and exocytosis, molecular sorting, epithelial transport, and hormonal responsiveness.[15-17] Culture of epithelial cells on porous substrates has been shown to allow establishment of polarity in vitro, thus permitting a more "in vivo-like" performance of normal cellular functions.[17] As such, our observations that epithelial cells obtained from secretory interval endometrium continued to express the TAG-72 epitope in culture, when grown as a polarized monolayer on biomatrix, were

A
B
C
D
E

consistent with descriptions of LS-174T colon cancer cell growth on plastic versus agar gels,[8] and confirmed our predictions.

We were surprised to find that, unlike the in vivo situation, endometrial epithelial cells obtained during the proliferative interval developed and maintained TAG-72 epitope expression after a short period in culture. This could be explained by the absence in vitro of one or more inhibitory factors, possibly of stromal origin, which are normally present during the proliferative interval in vivo. This notion is supported by descriptions of stromal regulation of epithelial cell function[18, 19] and a report of stromal-epithelial connections in the normal human endometrium.[20] Alternatively, the Matrigel biomatrix used in this study may contain factors that stimulate (or permit) glandular epithelial differentiation resulting in TAG-72 epitope expression. In this context, our observation that epithelial cells began to form apparent gland-like structures, when the thickness of the biomatrix permitted, may indicate that Matrigel components are directing or permitting some epithelial cell differentiated functions in vitro.



Normal endometrial epithelial cells cultured under the conditions described here exhibit monoclonal antibody B72.3 reactivity in vitro at a level consistent with that observed in vivo. Furthermore, in contrast to the marked heterogeneity of TAG-72 expression observed in vivo, cultures of endometrial epithelium on biomatrix exhibited almost uniform expression among all cells observed after 6 to 8 days of culture. Thus we believe that TAG-72 epitope expression by endometrial epithelial cells in vitro may prove to be a reliable marker for the study of factors that regulate endometrial maturation. This model could provide important information on the role of extracellular matrix and stromal components in modulating cellular differentiation in this dynamic tissue. Furthermore, understanding the regulation of TAG-72 epitope expression in the endometrium may provide insight into its regulation in neoplastic tissues.

The technical support of Vernon Summerlin, Lynne Black, and Mary Stevenson is gratefully acknowledged. We also thank Drs. Jeffrey Schlom and Barbara Vonderhaar for editorial comments.

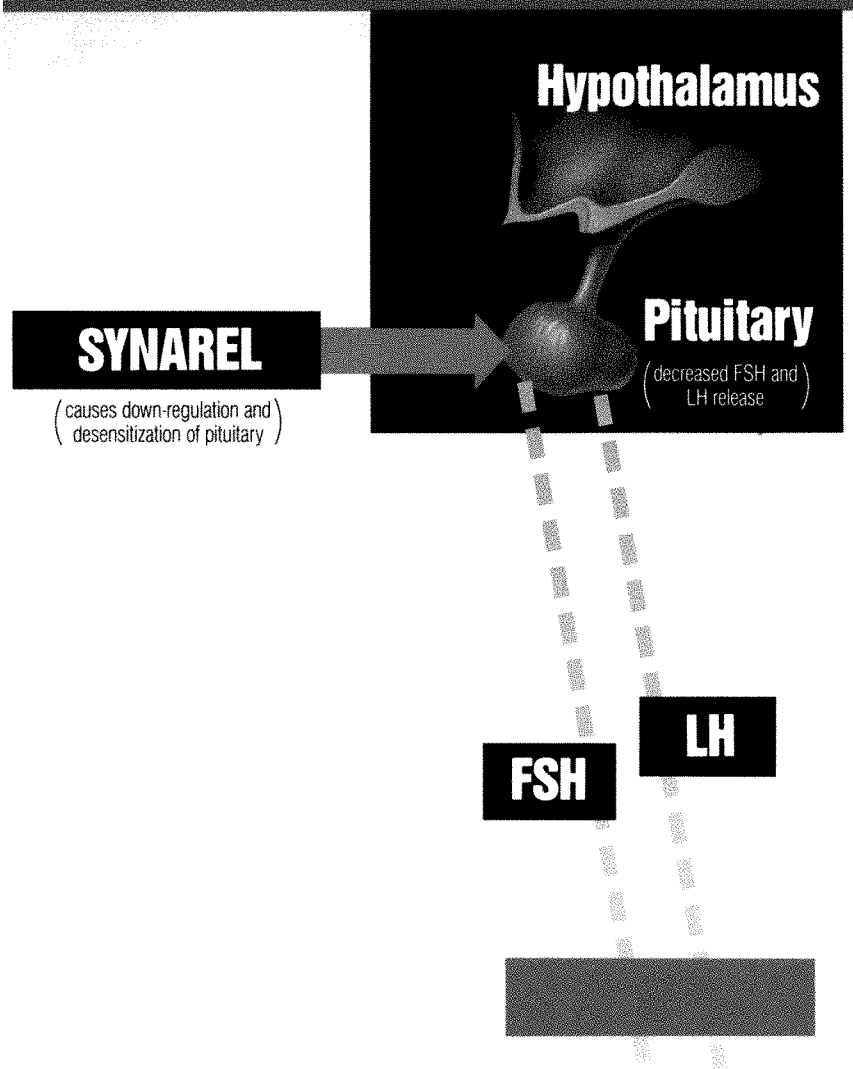
The intrauterine sound environment of the human fetus during labor

Susan Benzaquen, MD, Robert Gagnon, MD,* Cora Hunse, RN, and John Foreman, PEng
London, Ontario, Canada

Ten pregnant women near term with medical indications for internal monitoring during labor were studied to quantify the intrauterine sound environment. The intrauterine background noise was measured with a miniaturized hydrophone placed transcervically at the level of the fetal neck under ultrasonographic guidance. In eight women no cardiovascular noise was audible and the intrauterine noise consisted predominantly of low-frequency noise (<100 Hz) from 60 to 85 dB. Above 100 Hz, the sound pressure level was <60 dB, decreasing to 40 dB above 500 Hz. In only two women maternal cardiovascular sounds were audible during uterine relaxation and disappeared during uterine contraction. Maternal bowel sounds and maternal vocalization were well above the intrauterine background noise. Because of this relative quietness, we hypothesized that the fetal acoustic environment could be altered significantly during antenatal vibratory acoustic stimulation. (Am J Obstet Gynecol 1990;163:484-90.)



Key words: Fetal sound environment; effect of uterine contraction on intrauterine background noise; vibratory acoustic stimulation

In humans the fetal sound environment is believed to consist of loud pulsations from the maternal cardiovascular system, possibly from the main arteries and the placenta.[1,2] The overall sound pressure level in the pregnant human uterus has been reported to be as high as 95 dB.[1] More recently, in the chronically prepared pregnant ewe, the intrauterine background noise has been reported to be approximately 60 to 87 dB and increased by specific activities of the animal such as drinking.[3,4] Because of the increasing interest in the use of external vibratory acoustic stimulation in the assessment of fetal health,[5] it is important to determine the fetal sound environment under basal conditions. The purposes of this study were to quantify, in a group of pregnant women at term, the intrauterine sound environment during the active phase of labor and to determine the effect of uterine activity on the intrauterine background noise.

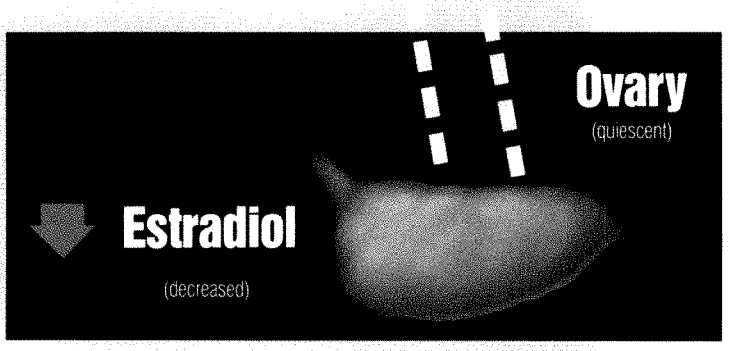
Patients and methods



Patients. Informed consent was obtained from 10 pregnant women between 37 and 42 weeks' gestational age (Table I). All women had medical indication(s) for internal monitoring (intrauterine pressure catheter and fetal scalp electrode for fetal heart rate tracing) during labor as illustrated in Table II. Six women had been placed under epidural anesthesia before the experi-

— SYNAREL Is Reliably Absorbed Through Nasal Mucosa

— Repeated Dosing Decreases FSH And LH Secretion

— Resulting Ovarian Quiescence Lowers Serum Estradiol, Leading To Relief Of Symptoms[1,2]

ment and four were unmedicated at the time the study was performed. All fetuses were singleton and in a vertex presentation at the time of delivery.

Experimental design. All studies began during the active phase of labor (>3 cm cervical dilatation; range 3 to 8 cm), after rupture of membranes, with patients resting in a recumbent position with a slight tilt to the left. After insertion of the fetal scalp electrode, an intrauterine pressure catheter (posteriorly to the fetal head) and a miniaturized hydrophone (anteriorly to the fetal head), the following measurements were obtained. A sound pressure level meter (model 2205, Bruel and Kjaer, Copenhagen) was used to record ambient overall sound pressure level in the labor room, at 1 cm from the surface of the maternal abdomen. Intrauterine background noise was measured during the peak of three uterine contractions and during three periods of uterine relaxation. The average of these three measurements was used to determine the sound pressure level spectrum for each patient during the two states of uterine contractility. Headphones also were used to listen to intrauterine sounds simultaneously as they were being recorded to identify any that were audible. After these baseline measurements, women were asked to pronounce *99* during uterine relaxation, to determine if maternal vocalization could be transmitted inside the uterine cavity. Instantaneous sound pressure level spectra were then obtained and stored for off-line analysis on floppy disks.

Measurements of intrauterine sound pressure levels. A real-time ultrasonographic scanner (model SAL-30A, Toshiba Corp., Shimoishi, Japan; 3.5 MHz transducer) was used to confirm the fetal presentation, the location of the fetal neck and the placenta, and the maternal abdominal wall thickness (maternal soft tissue thickness plus anterior uterine wall thickness). After insertion of the intrauterine pressure catheter and fetal scalp electrode, a custom-built miniaturized hydrophone (model No. 1, Sparton of Canada Ltd., London, Ontario) fitted to the end of a No. 16 polyvinyl nasogastric tube was inserted transcervically to the level of the fetal neck. The catheter was placed anteriorly to the fetal head in eight women and favored a slightly lateral position in two. In all women the hydrophone was placed above the fetal head at the level of the fetal neck and was in a pocket of amniotic fluid. Direct ultrasonographic visualization of the stainless steel body of the hydrophone (width of 9.5 mm) and turbulent flow produced around the hydrophone head by rapid infusion of sterile water into the nasogastric tube were used to confirm location of the miniaturized hydrophone.

The hydrophone was 19.1 mm long and 9.5 mm in diameter, with a flat frequency response from 400 Hz to 20 kHz (±2 dB). Below 400 Hz, the hydrophone sensitivity decreased by 5 dB at 300 Hz, 8 dB at 200 Hz, and 13 dB at 100 Hz, to a maximum of 23 dB at 10 Hz (sensitivity expressed as decibels per volt per 20 μPa). Therefore below 400 Hz sound pressure levels were corrected by means of specific sensitivity curves before final analysis. The electrical noise floor (decibels per 20 μPa per $\sqrt{\text{hertz}}$), which is the minimum sound pressure level that could be detected by the hydrophone, was 30 dB from 200 Hz to 15 kHz with a progressive rise to 33 dB at 100 Hz and a maximum of 55 dB at 10 Hz (as per calibration by Sparton of Canada). In comparison, the human ear can detect sound pressure level >30 dB at frequencies between 30 and 20,000 Hz.

The signal cable attached to the stainless steel body of the hydrophone was threaded through the lumen of the nasogastric tube and connected to a battery-powered preamplifier (Sparton of Canada). The output from the preamplifier was interfaced with an isolation line audiotransformer (model 195850G, Hammond, Willowdale, Ontario), and the output signal was processed by a real-time computer-based two-channel frequency analyzer (model 2630, Tektronix, Campbell, Calif.) and stored on floppy disks for off-line analysis. Calibrations of the hydrophone were done with electronically generated sounds of 94 and 114 dB (2×10^{-5} N/m^2) at 1 kHz (Department of Mechanical Engineering, University of Western Ontario) to determine a reference point for absolute sound pressure levels before and after each experiment. Fast Fourier Transform was done with a Hanning window, 1 kHz bandwidth, 1024 points, at a sampling rate of 2.56 kHz.

The average of 20 sound pressure level spectra for baseline intrauterine background noise and the average of two spectra during maternal vocalization were used to define one spectrum. The miniaturized hydrophone coupled with the preamplifier, the audio-transformer,

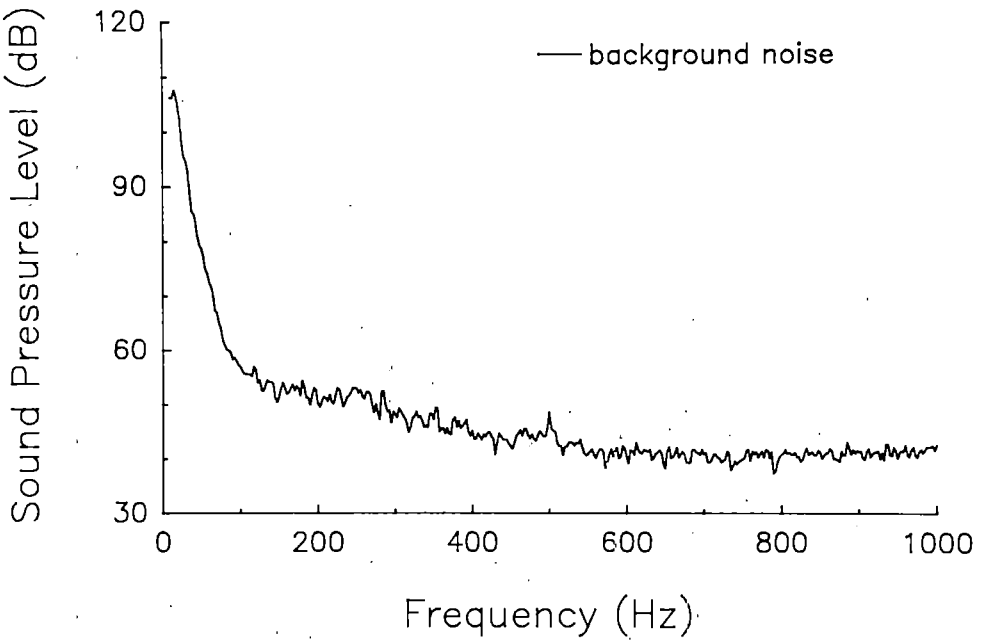

Fig. 1. Typical example of intrauterine background noise recorded at level of fetal neck (2×10^{-5} N/m^2.

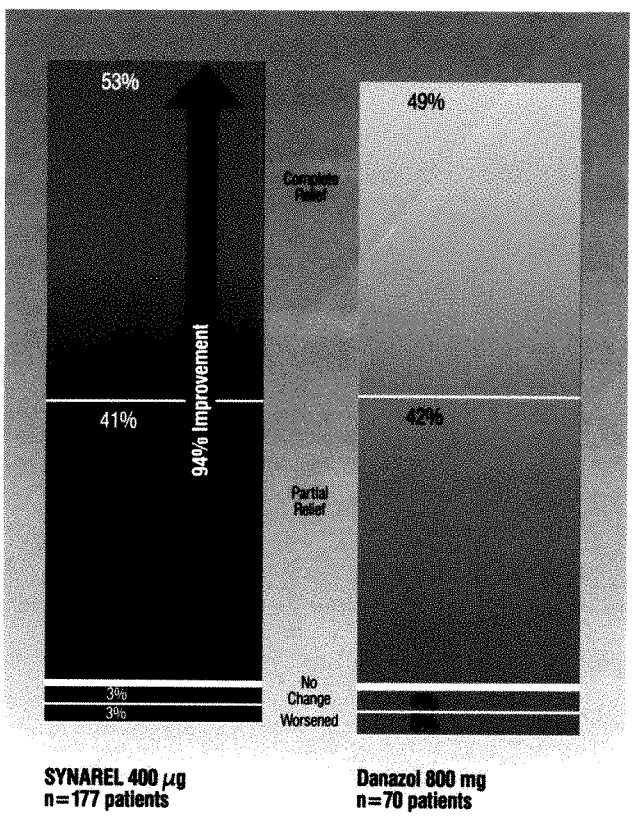
and the frequency analyzer were approved by the Canadian Standards Association for electrical safety as class risk III.[6] These standards are the same as for electronic internal fetal heart rate monitoring during labor and included: (1) a maximum allowable current leakage of <20 μA at patient-applied part regarded as source (5 μA for the hydrophone) and (2) a minimum dielectric strength test voltage at 60 Hz of 2500 V source for 1 minute, between accessible non-current-carrying metal parts and metal foil wrapped around the power supply cord at the point of entry in the housing.[6]

Fetal heart rate and uterine contractions were continuously recorded throughout the experiments on a Hewlett Packard 8040A (Hewlett Packard GMBH, Boeblinger, Federal Republic of Germany) cardiotocograph. At the end of each study, the hydrophone with the nasogastric tube was removed without any difficulty.

Data analysis. The overall ambient background noise (decibels) in the room was determined at the onset of each experiment. The absolute sound pressure level (decibels); 2×10^{-5} N/m^2) for each intrauterine sound spectrum obtained was determined automatically in 12.5 Hz increments from 12.5 Hz up to 1000 Hz, and the mean value was reported. All results are presented as means ± SEMs for each frequency. Statistical significance to examine the effect of frequency, uterine contractions, parity, epidural anesthesia, and placental location on sound pressure levels was determined by analysis of variance with repeated measures.

Results



Maternal cardiovascular sounds. The mean overall ambient noise as measured at 1 cm from the maternal abdomen was 55.9 ± 1.6 dBA (range 49 to 64 dBA). The frequency spectrum of the ambient noise consisted of low-frequency noise of 57 dB at 12.5 Hz decreasing to 40 dB at 60 Hz and 32 dB above 100 Hz. The mean maternal abdominal wall thickness was 3.1 ± 0.2 cm (range 2.3 to 4.5).

Fig. 1 shows a typical example of the intrauterine background noise during uterine relaxation. In eight out of 10 women, maternal cardiovascular sounds were not audible during uterine relaxation. The mean absolute sound pressure level was 97.4 ± 1.8 dB at 12.5 Hz, decreasing significantly to 59.2 ± 2.5 dB at 100 Hz, 48.4 ± 1.3 dB at 500 Hz, and 43.3 ± 0.4 dB at 1000 Hz (analysis of variance, $p < 0.001$) (Fig. 2). There was no significant difference in absolute sound pressure levels at any frequency between uterine relaxation and uterine contraction (Fig. 2).

In two women maternal cardiovascular sounds were clearly audible. The absolute sound pressure level during uterine relaxation in these two women was 19 dB higher at 100 Hz than in the eight women without audible cardiovascular sounds (78 and 59 dB, respectively, Fig. 3). At 650 Hz the difference in sound pressure level was only 2 dB. Below 100 Hz and above 650 Hz there was no difference in absolute sound pressure level between the two groups (Fig. 3). During uterine contractions, maternal cardiovascular sounds were no longer audible in these two women and the intrauterine

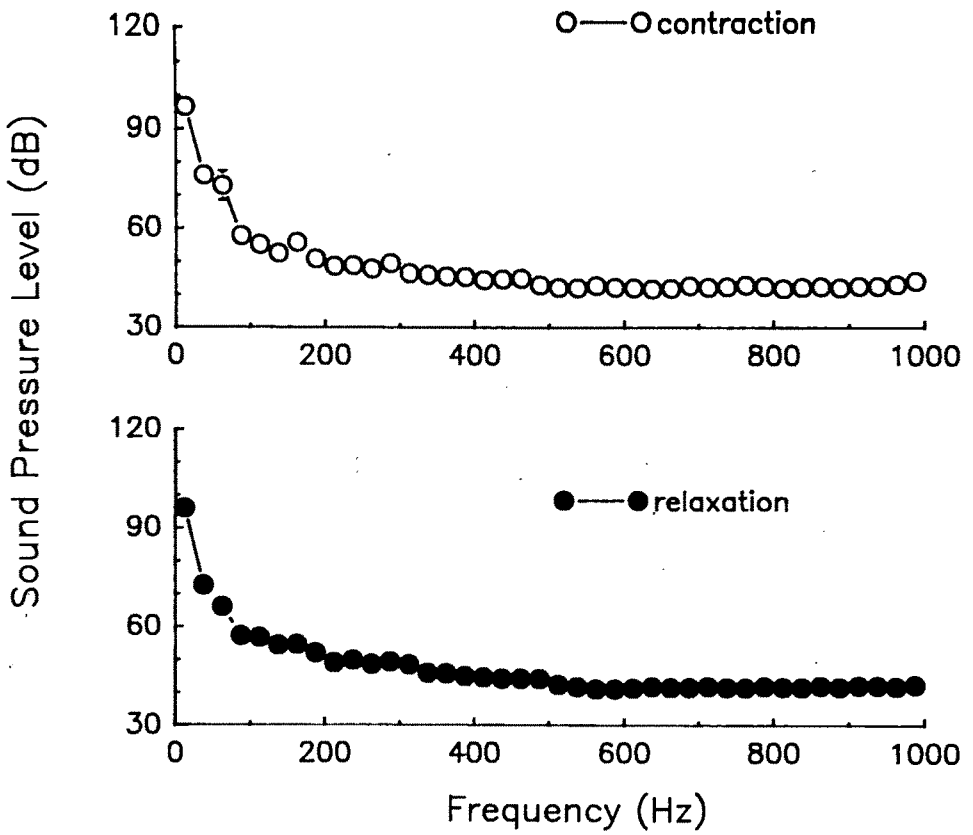

Fig. 2. Mean absolute sound pressure level (decibels; 2×10^{-5} N/m^2) (±SEM) was plotted in 12.5 Hz increments up to 1000 Hz during uterine contraction *(top)* and during uterine relaxation *(bottom)*. *Symbols* are larger than SEM.

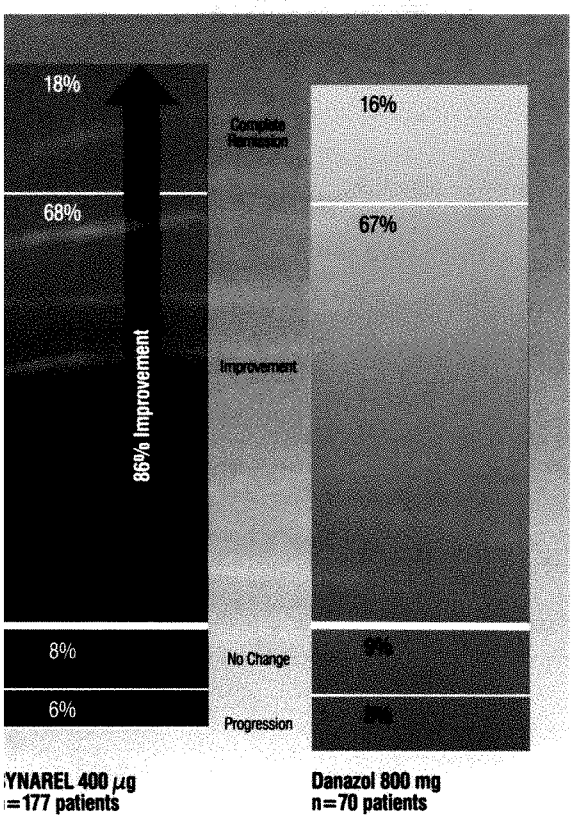
background noise was similar to that of the eight women without audible intrauterine vascular sounds (Fig. 3).

No significant difference was demonstrated in intrauterine sound pressure levels for primiparous women (n = 5) versus multiparous women (n = 5), for anterior placentas (n = 4) versus other locations (n = 6), and for women with epidural anesthesia (n = 6) versus those without medication (n = 4), in states of both uterine relaxation and uterine contraction.

Maternal bowel sounds and vocalization. In three women bowel sounds were audible during the experiment and were recorded simultaneously (Fig. 4). They consisted of two different qualitative types: one was a "low-pitched," "rumbling" sound (Fig. 4, top) and one was a "high-pitched," "tinkling" sound (Fig. 4, bottom). The sound spectrum was characterized by varying intensities between 40 and 60 dB at frequencies above 200 Hz. The same patterns of bowel sounds were seen in the three women studied.



Maternal vocalization was easily recorded in utero in the 10 women. The sound spectrum produced by pronouncing *99* was characterized by peak intensities of 70 to 75 dB at 200 to 250 Hz (which is the range of a normal female voice) and was approximately 20 dB above the intrauterine background noise at those frequencies (Fig. 5). A similar spectrum of sound was seen in all women during vocalization. The term *99*, as pronounced by the mother, was slightly muffled but clearly audible above the background noise.

Comment

The results indicated that the intrauterine sound environment of the human fetus during active labor predominantly consisted of low-frequency noise (<100 Hz) from 60 to 85 dB. Above 100 Hz the sound pressure level was <60 dB decreasing to 40 dB above 500 Hz. In our experimental conditions maternal cardiovascular sounds usually were not audible. Maternal bowel sounds and vocalization were well above the intrauterine background noise.

Many investigators have reported that maternal heart sounds in humans dominate the intrauterine sound environment and could contribute to fetal imprinting.[1, 2, 7] However, maternal cardiovascular sounds are not consistently detected from recordings of intrauterine background noise of pregnant ewes.[3, 4, 8, 9] Our data indicated that maternal vascular noise was clearly

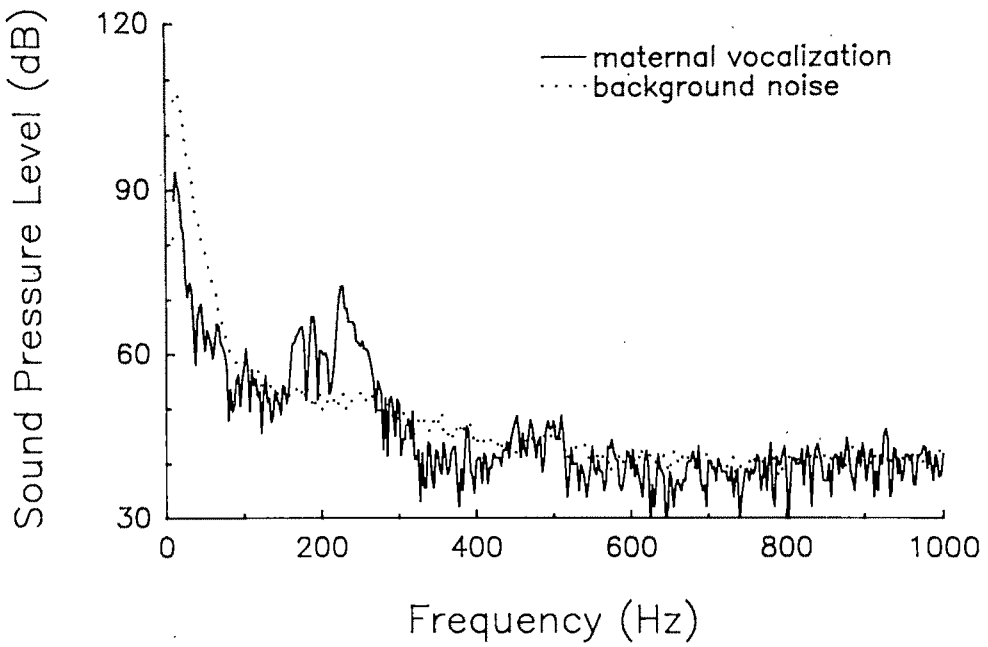

Fig. 5. Typical example of instantaneous intrauterine background noise during maternal vocalization *(solid line)* superimposed on average intrauterine background noise under basal conditions *(dotted line)* (2×10^{-5} N/m^2).

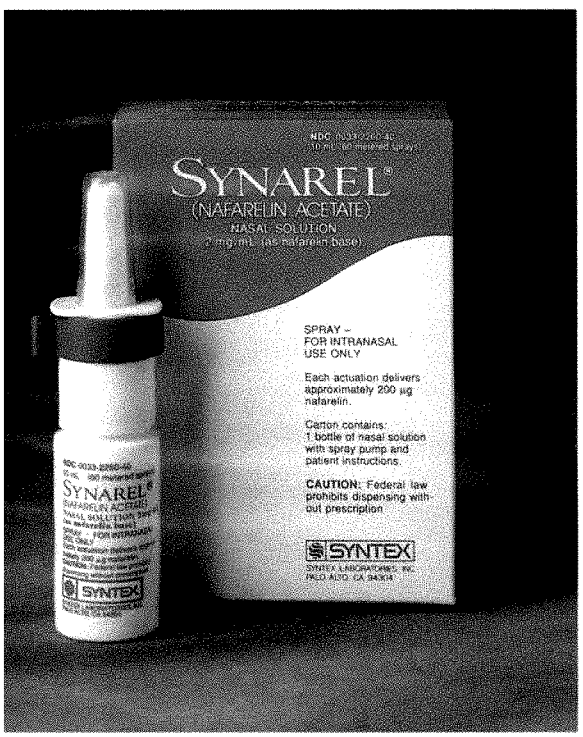
audible in only two out of 10 patients during uterine relaxation and disappeared during uterine contraction, suggesting that the hydrophone was sensing blood flow in the uteroplacental circulation, which is known to decrease during uterine contractions in labor.[10]



Using ultrasonographic guidance, we have been able to insert a miniaturized hydrophone anteriorly, at the level of the fetal neck, which is a location similar to that previously described in the pregnant ewe to record intrauterine background noise.[3] This technique contrasted with other human studies during which a microphone covered with a rubber sleeve was inserted either inside the vagina,[11] inside the cervix,[1] or posteriorly close to the maternal aorta.[12] These three anatomic regions are known to be well vascularized during pregnancy and could have contributed to the assumption that the intrauterine sound environment consisted mainly of loud vascular pulsations during human pregnancy.[1, 12]

The low-frequency component of the intrauterine background noise (<100 Hz) has been reported by Querleu et al.[12] in humans and by Vince et al.[3, 4] and more recently by Gerhardt et al.[9] in the pregnant ewe. Although it was believed to be due to maternal vascular sounds in humans,[2] it has also been measured after death of pregnant ewes.[9] It is possible that this low-frequency component of intrauterine noise was produced by the transmission of the external ambient noise by maternal soft tissues. However, the ambient noise at those frequencies was consistently below the intrauterine background noise, suggesting that the intrauterine noise was probably not affected by the room background noise. Our data suggested that this low-frequency component of intrauterine noise was not due to maternal blood vessels, digestive system, or vocalization during which very different sound spectra were identified.

The effect of uterine activity on intrauterine background noise has not been systematically reported before. In this study we have not been able to demonstrate any significant effect of uterine activity on the fetal sound environment. Vince et al.,[4] using a radiohydrophone implanted on the neck of one fetal lamb, recorded sound pressure levels during the active phase of labor in one pregnant ewe. They described that uterine contractions were accompanied by a slow buildup of loud sound produced mainly by the maternal cardiovascular system, breathing sounds, and sound generated by the restless behavior of the ewes. These observations may have reflected the difficult and protracted labor of this particular ewe as one of her lambs was noted to be malpositioned. In this study, like others,[3, 4, 8, 9, 12] maternal vocalization and intermittent bowel sounds were the major acoustic stimuli available to the human fetus when the extrauterine sound environment was relatively quiet. From the work of Fifer and Moon,[13] it has been suggested that newborn infants tend to suck more often in response to maternal voice than in response to other female voices. Our data suggested that it is possible to speculate that this early

responsiveness to mother's voice may be based on prenatal experience.

The data demonstrate that the intrauterine sound environment was relatively quiet (<60 dB at frequencies >100 Hz) interrupted by maternally generated sounds and not usually cardiovascular in origin. No significant difference was seen between uterine contraction and relaxation. Because of this relative quietness, it is possible that the fetal acoustic environment could be altered significantly during vibratory acoustic stimulation currently used in the evaluation of fetal health.[5] It remains to be determined to which sound intensity and frequencies the human fetus is exposed during such stimulation.

We thank Dr. John Patrick for his interest in this work, and Mrs. Maria De Sousa and Mr. John Ellis, PEng, for their excellent technical assistance.

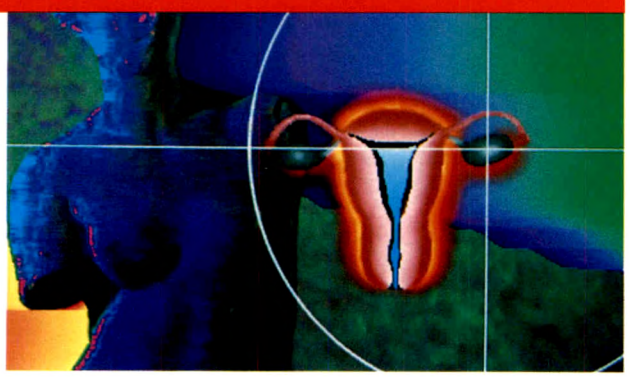
Effect of maternal-fetal movement on concentration of cells obtained at genetic amniocentesis

Stephen J. Carlan, MD, Peter Papenhausen, PhD, William F. O'Brien, MD, Marcello Pietrantoni, MD, Ronald A. Chez, MD, and Pamela Stephens, RN

Tampa, Florida



The number of viable amniotic fluid cells in the aliquot obtained at amniocentesis is an important determinant of the success of subsequent cell culture. However, cell concentration and viability are highly variable, even in samples of equivalent gestational age. We studied the effect of prescribed maternal position change or spontaneous fetal movement on the concentration, viability, and subsequent harvest time of amniotic fluid cells removed at genetic amniocentesis. Samples from 108 patients at 15 to 22 weeks' gestation were evaluated. We did not find a relationship between this type of maternal or fetal movement and the retrieval of amniotic fluid cells. (AM J OBSTET GYNECOL 1990;163:490-3.)

SYNTEX LABORATORIES, INC
PALO ALTO, CA 94304

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. Patients missing successive doses may experience breakthrough bleeding.

2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients.

3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician.

4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients.

5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content.

6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption.

7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4–8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4–8 weeks after discontinuation of SYNAREL may be misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

02-2260-40-00 © February 1990 Syntex Laboratories, Inc.

ence of adequate numbers of viable amniocytes. However, the concentration of cells and the proportion that are viable may vary widely between samples.[2]

A mechanism to increase the concentration of viable cells could increase the incidence of success and decrease the time to harvest. Controlling for gestational age, we studied the effect of a prescribed maternal position change or spontaneous fetal movement on the concentration, viability, and harvest time of cells obtained from second-trimester amniocenteses.

Material and methods

A total of 108 patients with singleton gestations scheduled for genetic amniocentesis between 15 and 22 weeks' gestation were enrolled in the study. Gestational age, placental location, fetal viability, and fetal number were confirmed with ultrasonography. The indications for the procedure included: advanced maternal age, 85 patients (78%); previous offspring with genetic disorders, 10 (9%); low maternal serum α-fetoprotein, 6 (5%), and others, 7 (6%). After informed consent was obtained the patient was randomized to either turn over 360 degrees on the examination table within 60 seconds before amniocentesis, or not turn. An amniocentesis using sterile technique with a 21-gauge spinal needle under continuous ultrasonographic guidance was then performed by either a fellow or faculty member of the Division of Obstetrics. A 5 MHz linear transducer (GE 3000) was used for all procedures. The placenta was avoided if possible. No aspirated fluid was discarded. Any specimen containing any degree of visible blood (even if it cleared immediately) was considered a bloody tap. Any fetal movement (regardless of the character of movement) that occurred during the procedure was noted. Normal fetal heart motion was ensured after the procedure before patient discharge. The amniotic fluid samples were immediately placed in plastic sterile containers at room temperature. Within 4 hours (before centrifugation) the fluid sample was studied for viability, cell type, and concentration. Viability was determined with trypan blue exclusion, and cell concentrations were calculated with a hemacytometer under light microscopy. Cell type was recorded as either epithelioid (large and flat), or mesenchymal (small and round).[3] Harvest times were adjusted for weekend work schedules. Results were analyzed with analysis of variance, with differences among the groups tested by use of Duncan's multiple range test.

Results

The average maternal age was 36 years (range, 18 to 41 years), and the average weight was 154 pounds (range, 105 to 342 pounds). Racial distribution of the patients was as follows: 95 white, seven black, five Hispanic, and one Oriental. Two punctures were required in five patients (4.6%), and there was a bloody tap in nine patients (8.3%). An average of 20 ml (range, 12 to 30 ml) of amniotic fluid was obtained. All cell cultures were successful, and there were no karyotypic abnormalities or major congenital anomalies detected by ultrasonography in this group of patients.

Table I. Distribution of gestational age and percentage of live cells

Completed gestational wk	*N*	*%*	*Average % live cells*	*Mean harvest time (days)*
15	17	16%	73	7.5
16	44	41%	66	7.7
17	18	17%	76	7.8
18	13	12%	72	7.0
19	8	7%	61	7.3
20	8	7%	53	6.8

Table II. Maternal-fetal movement groups

Group	*Maternal turn*	*Fetal movement*
1	Yes	Yes
2	Yes	No
3	No	Yes
4	No	No

When patients were grouped by gestational age, there was a trend toward decreasing concentration of live cells, especially in samples obtained after 18 completed weeks. Because of the relatively small sample size at this gestational age, however, we could not demonstrate a statistically significant gestational age effect on the number of live cells recovered or harvest time (Table I).

The patients were divided into four groups based on occurrence of maternal or fetal movement, or both (Table II). Mean cell type concentration and mean harvest time among the four groups are compared in Table III. Similar information was recorded after elimination of the 11 patients who had either a bloody tap or more than one needle insertion (Table IV). There was no statistical difference noted among the four groups. Similarly, when the groups were evaluated by gestational age, there was no statistically significant difference in the observed parameters.

Comment

There are several reasons for attempting to increase the number of viable cells obtained at amniocentesis. First, daughter cells in vitro may undergo secondary culture-induced chromosomal changes. Therefore it is important to have a clonal (in situ) evaluation of a large base of primary amniocytes to differentiate between true mosaicism and pseudomosaicism.[4-6] Second, increased cell numbers allow more flasks or cover slips

Diabetic ketoacidosis and insulin resistance with subcutaneous terbutaline infusion: A case report

Joseph M. Tibaldi, MD,[a] Daniel L. Lorber, MD,[a] and Alan Nerenberg, MD[b]
Flushing, New York

Diabetic ketoacidosis may occur in women treated with intravenous β-sympathomimetic agents for tocolysis. We describe diabetic ketoacidosis and transient severe insulin resistance in a woman with diabetes who was treated with subcutaneous terbutaline infusion. Subcutaneous terbutaline infusion may precipitate transient insulin resistance and diabetic ketoacidosis in women with diabetes. (AM J OBSTET GYNECOL 1990;163:509-10.)

Key words: Diabetes, ketoacidosis, terbutaline, tocolysis, insulin resistance

Diabetic ketoacidosis is a well-known complication of intravenous tocolysis with the β-sympathomimetic agents ritodrine and terbutaline.[1] Diabetic ketoacidosis has not been described with chronic oral use of either drug. Continuous subcutaneous infusion of terbutaline sulfate has recently been introduced for the treatment of preterm labor.[2] We report a patient with insulin-dependent diabetes in whom diabetic ketoacidosis developed during treatment with subcutaneous terbutaline infusion.

Case report

A 25-year-old woman with a 15-year history of insulin-dependent diabetes mellitus was admitted with uterine contractions noted on home uterine monitoring at 25 weeks of a twin gestation. Before admission her diabetes was well controlled with 50 to 60 units of insulin per day. Initial treatment with magnesium sulfate infusion was unsuccessful and treatment was begun with subcutaneous terbutaline via a battery-powered infusion pump (MiniMed model 404, MiniMed Technologies, Sylmar, Calif.) at a rate of 0.94 mg/24 hours with additional 0.25 mg boluses as needed. Total terbutaline requirements were between 2.0 and 3.0 mg/24 hours. Magnesium sulfate infusion was tapered and discontinued.

Before beginning the terbutaline infusion, the patient's plasma glucose level remained between 80 and 120 mg/dl on a constant infusion of 1 U/hr of regular insulin with 100 ml/hr of 5% dextrose. With addition of terbutaline her insulin infusion was increased to 4 U/hr. Despite this increase her plasma glucose level rose to 355 mg/dl with marked ketonuria and acidosis (bicarbonate, 11 mEq/L). Over the next 24 hours she required 110 units of insulin to resolve the ketoacidosis. At this time she began a diabetic diet and preprandial doses of regular insulin and HS NPH. On the third day of terbutaline infusion she required 126 units of insulin in divided doses. Insulin requirements than began to decrease; by the seventh day of terbutaline infusion her total daily insulin requirement was 77 units. Terbutaline infusion was maintained until the thirty-fifth week of pregnancy when cesarean section was performed. There were no further incidents of hyperglycemia or ketoacidosis.

Comment

Intravenous magnesium sulfate tocolysis is often successful in women with diabetes but hospitalization and careful monitoring are necessary. Intravenous but not oral administration of β-sympathomimetic agents is well known to cause metabolic decompensation with ketoacidosis in women with diabetes.

Oral tocolysis does not provide adequate maintenance for 40% to 50% of women with preterm labor and often repeat hospitalization for parenteral therapy is necessary. The development of portable, battery-powered, infusion pumps has made chronic parenteral therapy with subcutaneous terbutaline a viable alternative when oral tocolysis is unsuccessful.

Insulin resistance and ketoacidosis developed rapidly in our patient during treatment with terbutaline in a total dose of 2 to 3 mg per 24 hours, dramatically less than the usual intravenous or oral terbutaline dose of 40 to 60 mg/24 hours. Insulin requirements remained elevated for several days but fell to near-basal levels despite continued terbutaline infusion. This finding is probably explained by downregulation of adrenergic receptors with a decrease in hepatic glucose output, lipolysis, and ketogenesis.

to be set up, thus increasing the number of diagnostic mitoses and decreasing the time for completion. Finally, if a method of increasing the concentration of viable amniotic fluid cells could be discovered, less fluid would be required, which would be especially helpful in early amniocentesis.[7]

Resolution with current real-time ultrasonography is frequently adequate to discern turbulence echoes that appear when a second-trimester fetus moves suddenly. Agitation of a stable or resting system characterized by cells suspended in a liquid would intuitively appear to increase the likelihood of recovering more cells. The turbulence created should resuspend cells that have settled out, thus increasing the chance of their being obtained with the fluid sample. Therefore sampling the fluid immediately after a maternal movement, or during a fetal movement, should improve the cell yield.

In this study fetuses were observed to move during the procedure 68% of the time, and a maternal movement was prescribed 52% of the time. However, neither of these movements, alone or in combination, affected the concentration of cells in the sample obtained. Moreover, the specific type of cell recovered does not appear to be related to movement.

There are several other factors that may have influenced our results. Although there are different degrees of fetal movement, we did not specify the character of movement necessary to qualify for the "fetal movement" group. Any observed fetal movement was considered adequate. It is possible that a sudden forceful movement may create more agitation than the slow passive roll. Because turbulence echoes were not specifically documented, the data may not accurately reflect the effect of fluid agitation on cell recovery. Unfortunately, clear documentation of turbulence echoes, even if present, is not possible with every patient. The resolution of the ultrasonographic signal suffers as the distance from transducer to target lengthens. Thus turbulence may go unnoticed in obesity, advancing gestation, or in the deep pockets of the amniotic sac.

Second, a simple 360-degree maternal turn on the table immediately before amniocentesis may be inadequate to eliminate a "settling-out" effect, if present. However, more vigorous activity may be unacceptable to the patient.

Finally, the location of the needle point was generally just below the chorionic plate. This may not have been deep enough to detect any change in the amniocyte concentration produced by movement.

We conclude that agitation of amnionic fluid as produced by maternal or fetal movement in our protocol did not affect mean cell concentration, type, or harvest time obtained at genetic amniocentesis between 15 and 22 weeks. However, optimization of cell yield through a more effective combination of agitation and aspiration site selection may still be possible.

Continuous subcutaneous terbutaline infusion is an exciting new development in treatment of preterm labor. Its use is associated with a significant, albeit transitory, increase in glucose intolerance. This effect may be of little significance for the pregnant woman with normal glucose tolerance. For the woman with impaired glucose tolerance, gestational diabetes, or preexisting insulin-dependent diabetes, subcutaneous terbutaline may cause severe metabolic decompensation with hyperglycemia and ketoacidosis. Careful monitoring of plasma glucose and urine ketones is necessary with the institution of continuous subcutaneous terbutaline tocolysis.

A follow-up study of methods of contraception, sexual activity, and rates of trichomoniasis, candidiasis, and bacterial vaginosis

Fabio Barbone, MD, DrPH, Harland Austin, DSc, William C. Louv, PhD, and W. James Alexander, MD
Birmingham, Alabama

A randomized, clinical trial was conducted to evaluate the spermicidal agent nonoxynol 9 as prophylaxis for sexually transmitted diseases. Eight hundred eighteen women using birth control who attended a sexually transmitted disease clinic were evaluated monthly for trichomoniasis, candidiasis, and bacterial vaginosis for 6 months. Women using the active spermicide experienced a somewhat lower incidence rate of trichomoniasis (relative rate 0.83; 95% confidence interval 0.61 to 1.12) and bacterial vaginosis (relative rate 0.86; 95% confidence interval 0.69 to 1.12) as compared with placebo users. The rate of candidiasis was nearly identical for spermicide and placebo users (relative rate 1.02; 95% confidence interval 0.77 to 1.35). The number of sexual partners during the preceding month was related directly to the occurrence of trichomoniasis ($p = 0.047$) and bacterial vaginosis ($p = 0.009$) but not candidiasis ($p = 0.99$). Subjects using oral contraceptives experienced a statistically significant lower rate of trichomoniasis than did women using an intrauterine contraceptive device or who had had a tubal ligation (relative rate 0.56; 95% confidence interval 0.39 to 0.81). (Am J Obstet Gynecol 1990;163:510-4.)

Key words: Trichomoniasis, candidiasis, bacterial vaginosis, spermicide, oral contraceptives

Trichomoniasis, bacterial vaginosis, and candidiasis are common genital infections. Sexual transmission is the major cause of trichomoniasis[1] and probably is involved in most cases of bacterial vaginosis[2] and candidiasis.[3] However, the data regarding the evaluation of strategies for personal protection against these infections are limited. For example, although spermicides have been shown to inhibit the growth of *Trichomonas vaginalis* in vitro,[4] we are not aware of any clinical trials of spermicidal agents as a prophylaxis against trichomoniasis, bacterial vaginosis, or candidiasis. Furthermore, epidemiologic studies have found that spermicidal gels lower the risk of gonorrhea[5] and chlamydia.[6]

The prophylactic potential of a vaginal gel containing nonoxynol 9 on trichomoniasis, bacterial vaginosis, and candidiasis was evaluated in a randomized placebo-controlled trial. The design of the study also allowed

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

evaluation of the role of sexual transmission and oral contraceptive use on these infections.

Methods

The study design is described in detail elsewhere.[6, 7] Briefly, the study subjects were recruited from the sexually transmitted disease (STD) clinic of the Jefferson County Department of Health, Birmingham, from April 1984 through January 1986. The women volunteered to participate in a randomized, clinical trial of the spermicidal agent nonoxynol 9 as a prophylaxis against gonococcal and chlamydial infections. The subjects ranged in age from 19 to 29 years, were not pregnant, and were using and planned to continue using contraception (oral contraceptives, intrauterine contractive device, or a previous tubal ligation) for the next 6 months. This study was approved by the University's Institutional Review Board.

Subjects were assigned randomly to a group that was asked to use a commercially available spermicide containing a 3% concentration of nonoxynol 9 (408 women) or to a group using the vehicle for this product (410 women). Subjects were scheduled for monthly follow-up visits during a 6-month observation period. They were provided a calendar diary and instructed to keep a record of each sexual encounter they had during the previous month and whether the vaginal gel had been used. At each visit subjects were examined by a clinical nurse practitioner who palpated for enlarged lymph nodes, looked for skin lesions, inspected the perineal area, and performed a vaginal speculum examination and a bimanual pelvic examination. Endocervical cultures for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* were performed at each follow-up visit. If a subject had either of these two infections or any other STD, the appropriate treatment was provided. Subjects who were taking antibiotics or using intravaginal antibacterial or antifungal preparations were temporarily suspended from the trial until the prescribed antimicrobial therapy had ended.

The diagnosis of trichomoniasis was made by wet preparation if motile *T. vaginalis* organisms were present with or without an abnormal vaginal discharge.

Candidiasis was diagnosed by potassium hydroxide preparation showing yeast and/or hyphae with or without classic vaginal discharge or appearance.

Bacterial vaginosis was diagnosed by means of a positive amine test, a wet preparation showing clue cells, and an abnormal grayish discharge. Bacterial vaginosis was diagnosed only if at least two of the three criteria were met. pH was not evaluated because the study was conducted before the recommendation for inclusion of pH as a diagnostic criterion for bacterial vaginosis.

Statistical methods. The Cox proportional hazards model was used to estimate the relative rate of each infection as a function of exposure.[8] For a dichotomous exposure such as oral contraceptive or spermicide use, the relative rate is interpreted as the incidence rate of infection among the exposed divided by that among the unexposed. An advantage of the Cox model is that it allows for simultaneous control of many potential confounding (distorting) factors.

Most models included terms for age, race, spermicide category, birth control method, and sexual activity. However, since the study is randomized with respect to spermicide assignment, it is not necessary to adjust for these factors in the analysis pertaining to spermicide use (Table I). For this analysis the relative rate is estimated simply by dividing the infection rate among active spermicide users by the rate among placebo users. A confidence interval for the relative rate was obtained through the use of a method described by Rothman.[9]

If a subject was found to have trichomoniasis, candidiasis, or bacterial vaginosis at the initial examination, she was excluded from all subsequent analyses of that specific infection. Furthermore, if a woman was diagnosed with one of the three infections during the follow-up period, that event was counted in the analysis, but she was excluded from further analyses pertaining to that specific infection. Only first infections diagnosed during the observation period were counted because, although treatment was always provided after the diagnosis of these infections, test of cure was not always ascertained. Thus, to avoid counting the same infection twice, repeated infections were not considered. This procedure explains the slightly different length of the observation periods for the three infections.

Spermicide assignment and birth control method remained fixed during the 6-month observation period. On the other hand, the number of partners and the number of episodes of sexual intercourse each month varied during the follow-up period and were modeled accordingly. All p values in the report are two-tailed and 95% confidence intervals are used.

Results

Of the 818 subjects participating in the study, 617 were using oral contraceptives, 158 had been sterilized, and 43 were using intrauterine contraceptive devices. The median age of subjects was 23 years; 89% were black and the remainder were white; 18% were married.

Spermicide use. The effect of the use of the active spermicide compared with the placebo on the occurrence of trichomoniasis, bacterial vaginosis, and candidiasis is shown in Table I. Subjects using the active spermicide experienced a lower incidence rate of trichomoniasis and bacterial vaginosis, but the decrease is not statistically significant, either for trichomoniasis ($p = 0.21$) or for bacterial vaginosis ($p = 0.18$). The

Assessment of cerebral hemodynamics in pregnant women by internal carotid artery pulsed Doppler velocimetry

Tomoaki Ikeda, MD, and Norimasa Mori, MD
Miyazaki, Japan

To date, no studies have been done of serial changes in maternal cerebral hemodynamics during pregnancy. We used the noninvasive method of Doppler velocimetry to assess cerebral hemodynamics in pregnant women. Velocimetry measurements of the internal carotid artery were performed in 17 normal nonpregnant women and 77 women with uncomplicated pregnancies with a 4 MHz pulsed Doppler ultrasound system. Peak systolic and mean velocities in the first and second trimesters were almost the same as those in nonpregnant women, whereas they became slower in the third trimester. Pulsatility index from 4 to 31 weeks' gestation was significantly higher than in nonpregnant women, but fell to the nonpregnant value after 32 weeks. Doppler velocimetry was found to be an extremely useful method of cerebrohemodynamic evaluation in pregnant women. (AM J OBSTET GYNECOL 1990;163:494-8.)

Key words: Doppler, internal carotid artery, cerebral circulation, pregnancy

Marked changes in the cardiovascular system occur during pregnancy. Cardiac output and blood flow of organs such as uterus and kidney change drastically in pregnant women and have been measured by different methods. Little is known about cerebral hemodynamics in pregnancy,[1] although it is believed that pregnancy increases the risk of cerebrovascular compromise.[2] Traditional techniques for measurement of cerebral circulation are invasive to both mother and fetus and are time-consuming and expensive. Satomura and Kaneko[3] first used Doppler ultrasound for investigation of blood flow in 1960. Since then Doppler velocimetry has been used to measure the hemodynamics of various organs. In internal medicine and neurosurgery, Doppler velocimetry is used to evaluate cerebrovascular complications, especially stenosis and occlusions of main cerebral arteries. We present a preliminary study of cerebral hemodynamics in pregnancy using Doppler velocimetry of the internal carotid artery.

Material and methods

This study consisted of 17 nonpregnant women and 77 pregnant women referred from our outpatient clinic. Informed oral consent was obtained from all subjects. Pregnant women with a single fetus in utero were studied between 5 and 40 weeks' gestation. All had accurate pregnancy dating by early ultrasound biometry and had uncomplicated pregnancies.

infection rate of candidiasis was nearly identical for spermicide and placebo users. The results in Table I were nearly identical to those obtained from the use of a proportional hazards model, which allowed for the control of potentially confounding variables.

The percentage of times that the gel was used during vaginal intercourse was used as a measure of compliance. However, the relative rate of each infection for spermicide users compared with placebo users did not decrease consistently with increasing compliance.

Sexual activity. The number of partners and the number of episodes of sexual intercourse per month were used as measures of sexual activity. The number of sexual partners during the month preceding a follow-up visit (Table II) was related directly to the occurrence of trichomoniasis and bacterial vaginosis. A test for trend was statistically significant both for trichomoniasis ($p = 0.047$) and for bacterial vaginosis ($p = 0.009$). On the other hand, no positive association was found between number of sexual partners and the incidence of yeast infections (trend test: $p = 0.99$).

In contrast to the number of sexual partners, there was an inverse relation between the monthly number of episodes of sexual intercourse and trichomoniasis (trend test: $p = 0.004$) and candidiasis (test for trend: $p = 0.07$). There was little or no association between the rate of bacterial vaginosis and number of sexual episodes (trend test: $p = 0.88$) (Table III).

The use of antibiotics during the month preceding a follow-up visit was unrelated to the occurrence of candidiasis or to the other STDs. Therefore antibiotic use did not confound any of the associations described.

Oral contraceptive use. Women using oral contraceptives experienced a 44% lower infection rate of trichomoniasis (Table IV) than did women using an IUD or who had had a tubal ligation ($p = 0.002$). The relative rate of bacterial vaginosis for oral contraceptive users compared with nonusers also was below unity, but this deficit was not statistically significant ($p = 0.20$). On the other hand, the rate of candidiasis was higher among oral contraceptive users than nonusers, but this increase also was not statistically significant ($p = 0.21$).

Comment

Our results suggest that the use of a spermicide containing nonoxynol 9 protects against trichomoniasis and bacterial vaginosis. However, the magnitude of the protection was small and, since the findings are not statistically significant, they might be due to chance. In a recent cross-sectional study of women attending a

reproductive clinic, Feldblum et al.[10] reported that the prevalence of trichomoniasis and bacterial vaginosis was significantly lower among spermicide users than oral contraceptive users. However, since about 80% of the spermicide users in their study also used diaphragms, the protective effects may be due to diaphragms, or to a combination of the diaphragm and spermicides, rather than to spermicides alone. Another limitation of that study is that the associations were not adjusted for sexual activity, so that their findings may reflect simply increased sexual activity among oral contraceptive users compared with spermicide users. Our study subjects did not use diaphragms and our findings are not confounded by level of sexual activity. We also found a protective effect of spermicide use against trichomoniasis and bacterial vaginosis, but the protection was appreciably less than that reported by Feldblum et al., suggesting that their findings may have been confounded by diaphragm use and sexual activity. Nonetheless, the two studies taken together provide support for the idea that spermicide use protects against trichomoniasis and bacterial vaginosis.

Neither we nor Feldblum et al. found an association between spermicide use and candidiasis, whereas Rosenberg et al.[11] found that women using a contraceptive sponge containing nonoxynol 9 were more likely to be infected with *Candida* than women not using the sponge. These findings suggest that nonoxynol 9 alone does not increase the rate of infection by *Candida.* However, a combination of nonoxynol 9 and the sponge may increase the rate of candidiasis, or the apparent discrepancy between our findings and those of Rosenberg et al. may be due to different characteristics of the study subjects in Bangkok and in Birmingham.

Trichomoniasis has long been considered a STD.[12] Recent studies have demonstrated the absence of trichomoniasis in virginal female adolescents compared with sexually active adolescent girls.[13, 14] On the contrary, candidiasis and bacterial vaginosis have been isolated both in virgin women and in sexually active women.[14] Nonetheless, it is generally held that a high level of sexual activity also is a risk factor for candidiasis and bacterial vaginosis.

Our study confirms that number of sexual partners is a risk factor for trichomoniasis and bacterial vaginosis (Table II). However, number of partners was not as-

Internal carotid artery velocimetry was done with a pulsed Doppler system, TC2-64B (EME, Ueberlingen, Federal Republic of Germany) with a 4 MHz pulsed Doppler transducer. We used a modification of the method of Kirkham et al.,[7] positioning the probe just medial to the sternocleidomastoid muscle at the angle of the submandibular bone (Fig. 1, *B*). Transducer position and sample volume depth were adjusted until the most defined signals were obtained, keeping the angle between insonating beam and blood flow as low as possible. Our device uses a 64-point Fast Fourier Transform spectrum analyzer. The probe is 11 mm in diameter and uses a focused beam operating at depths of 7 to 77 mm electronically adjustable in 2.5 mm increments. Burst width is 2.6 μsec and axial extension 20 mm in the sample volume. We generally used a range of 0 to 100 cm/sec in which the pulse repetition frequency is 10 kHz. The wall thump high-pass filter is approximately 150 Hz and the low-pass filter is 9 kHz. The output is displayed as a time versus Doppler shift plot on a screen and it is stored as printed data.

The patient was placed at a 15-degree angle in a semirecumbent position with eyes open in a silent room during internal carotid artery velocimetry. Sweep speed was 4 seconds per screen with signals from both internal carotid arteries recorded for two screens each. Peak systolic velocities, mean velocities, and pulsatility indexes from each screen were averaged for each side (Fig. 1, *A*). Averages for the two sides were added and averaged again to obtain the final peak systolic velocity, mean velocity, and pulsatility index. Values of side differences were also calculated. The pregnant women were classified into nine groups for every four gestational weeks beginning from week 4. Where appropriate, significant differences were calculated by estimating the multiples of standard deviation and by Student's *t* test.

Results

Table I shows characteristics of the subjects. Each group of pregnant women was statistically similar to nonpregnant women in parity and age. Mean delivery date (±SD) of pregnant women was 39.0 ± 1.4 weeks of gestational age, and mean birth weight was 3044 ± 505 gm.

Values of internal carotid artery velocities in nonpregnant and pregnant women are shown in Table II and Figs. 2 and 3. Mean values of peak systolic and mean velocity in nonpregnant women were 61.2 ± 8.1 and 38.1 ± 6.3 cm/sec. Until 28 weeks of gestation, values of peak systolic and mean velocity in pregnant women were not statistically different from those of nonpregnant women. After 28 weeks, values of peak systolic and mean velocity fell significantly. In the 36- to 40-week group, peak systolic and mean velocity were 49.3 ± 8.7 and 28.4 ± 4.6 cm/sec, respectively, 19.4% ($p < 0.001$) and 25.5% ($p < 0.001$) less than those in nonpregnant women. Table II and Fig. 4 show pulsatility index in the internal carotid artery. Pulsatility index at 4 to 31 weeks' gestation was significantly higher than that in non-pregnant women. Pulsatility index af-

sociate with candidiasis in our study. On the other hand, the number of episodes of sexual intercourse was inversely related to the occurrence of trichomoniasis and candidiasis, whereas it was unrelated to bacterial vaginosis (Table III).

We consider multiple partners a better indication than number of sexual episodes of a sexual life style that would place a woman at increased risk of acquiring a STD. Thus we believe that our data support the notion that trichomoniasis and bacterial vaginosis are sexually transmitted, despite the observations that trichomoniasis is inversely related and bacterial vaginosis is unrelated to number of sexual episodes. On the other hand, the finding that candidiasis is unrelated to number of sexual partners suggests that sexual transmission is not a major cause of yeast infections among our subjects. The inverse relationship between number of sexual episodes and trichomoniasis and candidiasis may be due to a reduction in sexual episodes because of symptoms of these genital infections in the weeks preceding their diagnosis. A paucity of symptoms of bacterial vaginosis may account for the absence of a similar effect on sexual activity.

The most striking finding of this study is that oral contraception appears to be a strong protective factor against trichomoniasis. The validity of this finding is enhanced by the observations that oral contraceptive use was not significantly associated with bacterial vaginosis and candidiasis (Table IV). Furthermore, Louv et al.[7] reported that oral contraceptive use increased the infection rates for both chlamydia and gonorrhea among these women. It is unlikely that some source of bias or confounding could have affected the results of these different genital infections in opposite directions.

The protective effect of oral contraceptive use on trichomoniasis is supported by a sparse but consistent epidemiologic literature. In a 1979 British case-control study,[15] the relative risk of trichomoniasis was 0.5 (95% confidence interval 0.29 to 0.85) for oral contraceptive users compared with nonusers. In a cross-sectional study of women attending a STD clinic in the United Kingdom,[16] the relative prevalence of trichomoniasis was 0.67 (95% confidence interval 0.49 to 0.91) for oral contraceptive users compared with nonusers. This latter study controlled for number of sexual partners as a possible confounder. Our study compared oral contraceptive users with women using intrauterine contraceptive devices or those who had had a tubal ligation. Since the association is adjusted for age, race, education, marital status, parity, number of sexual partners, and number of sexual episodes, confounding by these factors should have been eliminated. Furthermore, chance is an unlikely explanation of the finding because of the small p value, and we cannot identify any other plausible explanation of the finding other than causality.

In a recent article it was reported that *T. vaginalis* possesses estrogen receptors and that 17β-estradiol increases its growth.[17] Furthermore, the binding of 17β-estradiol was inhibited by the antiestrogen tamoxifen citrate. Since endogenous estrogens enhance the growth of *T. vaginalis*, we speculate that oral contraceptives could compete with them for the same receptors, ultimately protecting from *T. vaginalis* infection. Oral contraceptives also could modify the characteristics of the cervical mucosa and reduce the ability of *T. vaginalis* to infect it.

In summary, we found a strong protective effect of oral contraceptive use against trichomoniasis and a weak, statistically nonsignificant, protective effect of spermicide use on trichomoniasis and bacterial vaginosis. Multiple sexual partners was a risk factor for trichomoniasis and bacterial vaginosis but not for candidiasis.

Comment

Whether cerebral blood flow can be estimated by internal carotid artery velocimetry is debatable. In 1980 Risberg and Smith[5] reported a high correlation between values of internal carotid artery velocimetry and those of cerebral blood flow by the xenon 133 inhalation technique. They found a correlation coefficient of 0.88 ($p < 0.001$) between right hemispheric blood flow and internal carotid end-diastolic velocity in the right side, and 0.83 ($p < 0.001$) in the left side.

When the values of internal carotid artery velocimetry are interpreted as an index of cerebral blood flow, several factors must be considered. Velocity, not flow, was measured. Because no precise noninvasive methods are available, we did not measure arterial diameter. The fact that excellent correlation between the values of internal carotid artery velocity and hemispheric cerebral blood flow was demonstrated in the study by Risberg and Smith[5] without regard to arterial diameter suggests that our data reflect actual cerebral blood flow. It is not likely that the diameter of a large artery such as the internal carotid artery changes during pregnancy.

The angle between ultrasound beam and vessel must be kept constant among cases because velocity values are in part dependent on the angle. In this study we attempted to keep the insonating angle as parallel to the vessels as possible, however, zero degrees could not be obtained because of the anatomic position of the internal carotid artery. If the angle between the blood velocity vector and the beam is less than 20 degrees, variations in velocity are mathematically determined to be less than 6%. In our study, in which the same examiner performed all measurements, variation in angle between the vessel and insonating beam was believed to be less than 20 degrees.

The brain is supplied by two primary blood flows, the carotid and the vertebrobasilar systems. Measurement of carotid velocity alone does not completely assess the entire brain blood supply. Contribution of the vertebrobasilar system was estimated to be approximately 10% by Hardesty et al.,[6] but its extent remains controversial.

Although the factors previously described may be a source of error when cerebral blood flow is assessed by internal carotid artery velocimetry, this method is the most suitable for the study of cerebral hemodynamics in pregnant women because of its noninvasive, simple, and instantaneous character.

There are no reports of serial changes in maternal cerebral circulation. Cerebral blood flow in pregnant women was described by McCall[1] in 1949 in a study of nine normal young women between 34 and 40 weeks' gestation and 29 patients with toxemia of pregnancy using Ketty and Schmitt's nitrous oxide method. Cerebral blood flow in late pregnancy was much the same as that in normal young adult men. These results seem incompatible with our results. The earlier study was unsatisfactory because values of pregnant women were not compared with those of nonpregnant women but with those of men.

Two recent investigations have shown that cerebral blood flow in women is greater than that in men. Grolimund and Seiler[7] performed internal carotid artery velocimetry with the same techniques as ours except that they used pulsed 2 MHz frequency ultrasonographic Doppler rather than 4 MHz. They demonstrated that the mean (±SD) velocity of the internal carotid artery in women (mean age, 55.6 years) was 39.2 ± 9.3 cm/sec and statistically greater than that in men (mean age, 55.4 years), 34.3 ± 7.5 cm/sec ($p < 0.00005$). They speculated that the difference of mean velocity values between men and women was partially a result of the lower hematocrit of women, which reduces viscosity of blood and thus increases cerebral blood flow. Devous et al.[8] measured regional cerebral blood flow in 97 normal subjects (56 men, 41 women) quantitatively with the inert gas washout technique with xenon 133 and single-photon emission computed tomography. They found that regional cerebral blood flow in women was higher than in men at all ages with statistical significance in the 20- to 29-year old ($p = 0.01$) and 30- to 39-year-old ($p = 0.03$) groups.

Bacterial vaginosis: Diagnostic and pathogenetic findings during topical clindamycin therapy

Charles H. Livengood III, MD,[a] Jessica L. Thomason, MD,[b] and Gale B. Hill, PhD[a]
Durham, North Carolina, and Milwaukee, Wisconsin

We examined subjective and objective correlates among 67 women with symptomatic bacterial vaginosis before and after treatment with intravaginal clindamycin or placebo. We found no preponderance of any sexual practices among these patients. Nine patients (13.4%) had had hysterectomy. Whereas odor and discharge were the most common symptoms, 30 patients (44.8%) also complained of vulvovaginal irritation. Symptoms correlated poorly with objective therapeutic outcome. On examination the diagnosis would have been missed in seven patients (10.4%) if the clinician relied on presence of an abnormal vaginal discharge to suggest bacterial vaginosis. Vaginal pH >4.5 was found immediately after curative therapy in 59.6% of patients. *Mobiluncus* spp. morphotypes were 99.0% specific and 52.1% sensitive and proline aminopeptidase activity in vaginal fluid was 84.4% sensitive and 70.2% specific for diagnosis. Our Gram stain criteria yielded no false-negative results, 6.1% false-positive, and frequent indeterminate results after therapy. We found little evidence for sexual transmission of bacterial vaginosis. Recurrence after effective therapy was not predicted by vaginal pH elevation, positive or indeterminate Gram stain result, or positive proline aminopeptidase test. (Am J Obstet Gynecol 1990;163:515-20.)

Key words: Bacterial vaginosis, vaginitis, sexually transmissible disease, proline aminopeptidase, *Mobiluncus* spp.

There have been important evolutionary steps in our understanding of bacterial vaginosis since it was described under the name of *Haemophilus vaginalis* vaginitis by Gardner and Dukes in 1955.[1] New laboratory diagnostic tests of vaginal fluid have been developed, including Gram stain,[2] gas-liquid chromatography,[3] and proline aminopeptidase testing.[4] Clinicians have come to understand that the involvement of *Haemophilus* (now *Gardnerella*) *vaginalis* may be incidental, and that the characterization of this condition is replacement of *Lactobacillus* spp. by various anaerobic bacteria as the dominant vaginal flora.[3, 5] Although clearly associated with bacterial vaginosis, the role of *Mobiluncus* spp. remains uncertain.[6]

The cause of bacterial vaginosis is not known, nor is the reason for frequent recurrences in some women. Some studies have suggested that it is a sexually transmitted disease,[5, 7] but other studies have not found evidence for such a cause.[8-10] Whether various components of the diagnosis, for example the relative alkalinity of vaginal fluid, represent cause or effect is not known. Although bacterial vaginosis is found in 50% of women with an intrauterine contraceptive device in situ[7] and in 86% of those with vaginal trichomoniasis,[11] it is also found commonly in their absence. The common thread(s) that results in bacterial vaginosis among these women has not been identified.

The signs and symptoms of bacterial vaginosis are variable and often subtle; up to 50% of some affected patient groups are asymptomatic.[9] Thus, although current data suggest that this process may be involved in important upper genital tract complications in pregnant[12] and nonpregnant women,[13, 14] the diagnosis of bacterial vaginosis may not be suspected with appropriate frequency until clinicians are afforded an adequate understanding of its presentation.

In a recent study of the use of topical clindamycin in the treatment of bacterial vaginosis, we gathered data to attempt to elucidate some of these issues regarding the clinical presentation, diagnosis, and pathogenesis of this disease.

Material and methods

Women with any vaginal symptoms seen in the gynecology clinics of the two centers that conducted this study were evaluated for the presence of bacterial vaginosis. The following conditions excluded patients from participation in this study: age less than 18 or greater than 45 years, allergy to clindamycin, premenarchal or postmenopausal, pregnancy or lactation, use of any systemic or intravaginal antibacterial agents dur-

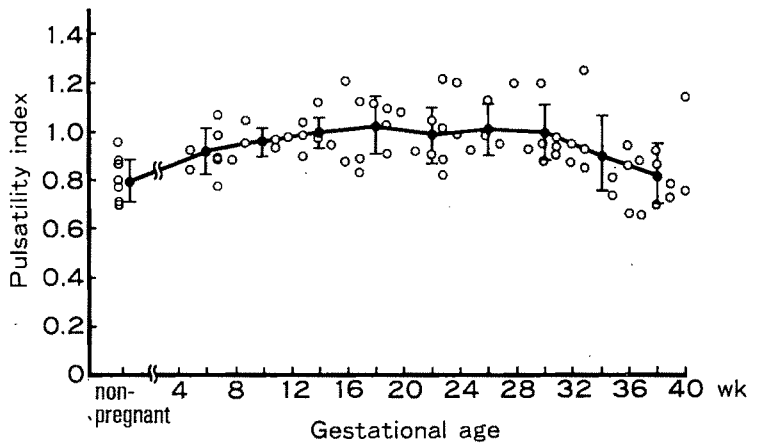

Fig. 4. Pulsatility index in internal carotid artery in nonpregnant women and women with uncomplicated pregnancies. *Open circles* indicate mean values of right and left carotid arteries. *Bars* represent mean ± SD.

Considering the predominance of cerebral blood flow in women, the studies by McCall[1] indicate that the high flow level in nonpregnant women becomes a low flow level in late pregnancy because it is then equal to the flow level in men. This is in agreement with our results.

Mean velocities in the internal carotid artery in the first and second trimester were almost equal to those in the nonpregnant state but were reduced by approximately 20% in the third trimester, indicating a reduction in cerebral blood flow. Although the causes of this change are unclear, chemical factors induced by pregnancy, such as hypocapnia and metabolic acidosis, or physical factors, such as increased cardiac output in pregnancy, or both, appear to affect cerebral hemodynamics. Increased pulsatility index values between 4 to 31 weeks' gestation may be caused by increment of stroke volume rather than increase of cerebrovascular resistance, because pulsatility index not only represents downstream vascular resistance of the cerebral vascular beds but also variables upstream from the point of measurement, such as cardiac output and stroke volume.[9] It is interesting to note that velocity in the internal carotid artery decreases during the third trimester of pregnancy when incidence of cerebral arterial occlusion is higher than during other trimesters.[2]

Doppler velocimetry of the internal carotid artery was found to be highly useful in studying cerebrohemodynamics in pregnancy. More investigation is needed to explain factors responsible for changes in cerebral circulation in pregnancy.

ing the 2 weeks before enrollment, history of antibiotic-associated colitis or frequent diarrhea, requirement for other ongoing antibiotic therapy, an intrauterine contraceptive device in place, previous entry into this study, the presence of mucopurulent cervicitis, vaginal candidiasis, herpes genitalis, or trichomoniasis, presently menstruating, or Gram stain of vaginal secretions not consistent with bacterial vaginosis.

Patients who were not excluded who were determined to have bacterial vaginosis and who gave written informed consent to participate were entered into the study. Bacterial vaginosis was defined as follows: the presence of clue cells on wet-mount slide (vaginal secretions mixed with saline solution and examined by high-dry microscopy) plus at least two of the following conditions: (1) vaginal discharge pH >4.5, (2) an increased thin homogeneous vaginal discharge, (3) release of a fishy (amine) odor from a sample of the discharge after addition of 10% potassium hydroxide (sniff test). A clue cell was defined as a squamous epithelial cell so heavily studded with bacterial forms that the cell border was obscured.

Vaginal Gram stains were classified according to a modification of the criteria of Spiegel et al.[2] as follows: consistent with bacterial vaginosis—predominating and large numbers (3+ to 4+) of mixed bacterial types including *Gardnerella* morphotype and other gram-positive or gram-negative rods or cocci or both, with *Lactobacillus* morphotype in the minority or absent among total vaginal flora and fungal forms absent; normal—Lactobacillus morphotype clearly predominant among total vaginal flora, with or without *Gardnerella* morphotypes, and fungal forms absent; indeterminate—those cases meeting criteria for neither normal nor consistent with bacterial vaginosis. During Gram stain evaluation the presence or absence of curved rods morphologically consistent with *Mobiluncus* spp. was recorded.

When eligibility for study enrollment was thus confirmed, patients were interviewed to gather epidemiologic data, genital tract symptoms, and medical and sexual history. During pelvic examination vaginal discharge was collected from the anterior and lateral fornices for pH testing, wet-mount microscopic examination in saline solution and potassium hydroxide, sniff test, Gram stain, proline aminopeptidase testing,[4] and culture for fungi, trichomonads, and herpes virus. Endocervical swabbings were obtained to rule out the presence of *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Patients were then provided in a double-blind fashion with either clindamycin phosphate cream at a concentration of 0.1%, 1.0%, or 2.0% or placebo cream (respective pH 6.0, 5.7, 5.4, 6.2) for vaginal administration, 5 gm twice daily for 5 days. They were instructed to use condoms during intercourse and to refrain from use of any other vaginal agents and systemic antimicrobial therapy.

Patients were seen for outcome evaluation at 4 to 7 days and again at 1 month after completion of therapy and classified as follows. Cure was defined by absence of clue cells (i.e., normal squamous cells) in vaginal fluid on wet mount plus presence of at least two of the following three: (1) grossly normal vaginal discharge (defined as translucent white, flocculent, low volume), (2) vaginal pH ≤4.5 , and (3) negative sniff test. If criteria for cure were not met, the case was declared a therapeutic failure. Nonevaluable patients were those patients who used fewer than eight doses of medication on schedule, failed to return for the first follow-up visit, had a positive test for another lower genital tract pathogen from the enrollment visit, or used any other intravaginal or systemic antibacterial agent before the first return visit. Cases that were declared therapeutic failures were offered therapy with open-label 1% clindamycin cream and were reevaluated as in the blinded therapy protocol.

Therapeutic results[15] did not differ significantly as a function of clindamycin concentration in the creams; 43 of 46 patients (93%) and 35 of 39 (90%) were cured 1 week and 1 month, respectively, after active drug therapy compared with four of 16 (25%) and three of four after placebo therapy. When open-label treatment results are included, the cure rates were 56 of 61 (92%) and 37 of 44 (84%) 1 week and 1 month after active drug therapy.

Statistical techniques used for data analysis were χ^2 test, Fisher's exact test, or the randomization test as appropriate.

Results

Sixty-seven symptomatic patients with pure (all cultures for other lower genital pathogens were negative) bacterial vaginosis were enrolled. Their epidemiologic characteristics are presented in Table I. Further examination of these patients with pure bacterial vaginosis who supplied sexual history (N = 66), reveals that 33 (50.0%) participated in oral-vaginal sex before onset of bacterial vaginosis symptoms, and 2 of 33 (6.1%) discontinued this practice after onset of those symptoms; 3 of 66 (4.5%) related onset of symptoms to initiation of oral-vaginal sex. A history of penile-anal intercourse was found in only two patients (3.0%). Four (6.1%) patients related onset of symptoms to initiation of penile-vaginal sex or a new sexual partner. Genital symptoms in current sexual partners were described by eight of the 67 (11.9%) patients with pure bacterial vaginosis, penile dermatitis symptoms in five, and urethritis symptoms in three. Other genital tract disease was present in seven patients among those with pure bacterial vaginosis (endometriosis in five patients, hy-

Changes in active and latent collagenase in human placenta around the time of parturition

Mohammad R. Rajabi, MD,[a] David D. Dean, PhD,[b] and J. Frederick Woessner, Jr., PhD[b, c]
Miami, Florida

High levels of collagenase are present in cervical extracts and in the circulation in women at parturition. This study examines the content of collagenase in human placentas at term, the possible contribution to circulating enzyme, and the changes that occur at parturition. Active and latent forms of collagenase are detectable in placentas with apparent relative molecular mass of 60,000 and 65,000 d, respectively. Gel-filtration chromatography was used to identify the presence of excess tissue inhibitor of metalloproteinase as the major collagenase inhibitor in the extracellular matrix of human placentas. After the onset of labor, there was a significant increase in total collagenase activity. Inactivation of the tissue inhibitor of metalloproteinase by reduction of placental extracts with dithiothreitol and alkylation with iodoacetamide resulted in a twelvefold to seventeenfold increase in collagenase activity. Umbilical cord collagenase levels were significantly lower than those in maternal circulation. The possibility of circulating collagenase originating from placenta in labor is discussed. (Am J Obstet Gynecol 1990;163:499-505.)

Key words: Human placenta, collagenase, tissue inhibitor of metalloproteinase, parturition

Human placenta plays a central role in the growth and development of the fetus. In addition to controlling the vital functions of nutrition and respiratory gas exchange to the fetus, it is involved in the biosynthesis of steroid and peptide hormones and growth factors.[1] This complx organ is also of interest because it is a rich source of collagen. The fibrillar collagen types I and III account for >90% of the total placental collagen at term; the remaining collagen is mainly types IV and V.[2] When human placenta synthesizes collagen in organ culture approximately two thirds of the collagenous proteins produced are of types I and III.[3] Several reports indicate that the placenta is rich in cysteine proteinases such as cathepsin B, collagenolytic cathepsin, and calcium-activated neutral proteinases.[4-7] These cysteine proteinases participate in the degradation of intracellular and extracellular matrix proteins. The presence of cysteine proteinase inhibitors in human placenta[8] supports a regulatory function for these proteases.

Although cysteine proteinases are capable of degrading telopeptide ends of fibrillar collagen, the process of collagenolysis cannot occur at physiologic pH without cleavage of the collagen triple helix by collagenase. We have previously shown that extracts of human placenta at term contain collagenase[9] and that collagenase is implicated in the mechanism of dilatation of the uterine cervix in women at parturition.[10] High levels of collagenase were present in cervical extracts and in serum at delivery.[9, 10] The source of serum collagenase in women has not been identified. One may speculate that enzymatic degradation of placental collagen and other components of the extracellular matrix becomes important near parturition when the placenta must separate from the uterine wall.

This study was undertaken to optimize detection of collagenase in human placenta and to investigate possible changes in the activity of this enzyme at parturition. The relationship between collagenase in maternal and fetal compartments was also determined.

Material and methods

Material. Chemical reagents were obtained from the following sources: [^{3}H]acetic anhydride (50 mCi/mmol) and Aquasol scintillation fluid (New England Nuclear, Boston); bovine trypsin (crystallized × 3, 180 U/mg, Worthington Enzymes, Freehold, N.J.); bovine chymotrypsin (crystallized × 3, 153 U/mg), ethylenediaminetetraacetic acid, 1,10-phenanthroline, and Brij 35 (polyoxyethylene 23 lauryl ether, Sigma Chemical Company, St. Louis); aminophenylmercuric acetate (practical grade, ICN-K + K Laboratories, Plainview, N.Y.). Polypropylene Chemtube containers were purchased from Bio-Rad Laboratories (Richmond, Calif.).

Tissue specimens. Human placentas were obtained

Uterine, adnexal tenderness	9	13.4
Increased thin homogenous vaginal discharge	60	89.6
Vaginal pH >4.5	64	95.5
Positive sniff test	62	92.5

*Inflammation: any of erythema, edema, tenderness.

poplastic vulvar dystrophy in one, and anovulation in one).

Table II expresses the frequency of symptom constellations among the 67 patients with pure bacterial vaginosis; symptoms were assessed only categorically, not quantitatively. When individual symptoms are examined with or without other symptoms, vaginal discharge is found in 61 (91.9%), followed by vaginal odor in 49 (73.1%), irritative symptoms in 30 (44.8%), and 3 (4.5%) each with complaints of abnormal bleeding and urinary symptoms.

Table III shows the examination findings at the time of entry into the study for all 67 patients with pure bacterial vaginosis. Inflammatory changes on examination were found in 20 of 67 (29.9%) patients with pure bacterial vaginosis, comparable to the frequency of symptoms of vulvovaginal irritation reported. All criteria for diagnosis were present in 52 of 67 (77.6%) patients, whereas seven (10.4%) lacked the characteristic discharge, five (7.5%) lacked the positive sniff test, and three (4.5%) had a vaginal pH ≤4.5.

Curved rods resembling *Mobiluncus* spp. were found in 36 of the 67 patients (53.7%). Proline aminopeptidase activity in vaginal fluid from patients with pure bacterial vaginosis was positive in 27 of 34 (79.4%). Proline aminopeptidase activity was positive in 25 of 30 (83.3%) patients with all criteria for bacterial vaginosis present, both of two patients who lacked the positive potassium hydroxide sniff test, and neither of two with vaginal pH was ≤4.5. Sixteen of 18 (88.9%) patients with and 11 of 16 (68.8%) patients without curved rods on vaginal smear were positive for proline aminopeptidase activity ($p > 0.05$ for all comparisons).

Analysis of the relationships between patients' symptoms and presence of objective criteria for the diagnosis of bacterial vaginosis after treatment revealed a poor correlation. Resolution of all vulvovaginal symptoms did occur more frequently among patients cured by objective criteria after blinded treatment (29 of 47, 61.7%), but not significantly more frequently than among patients with persistent disease by objective cri-

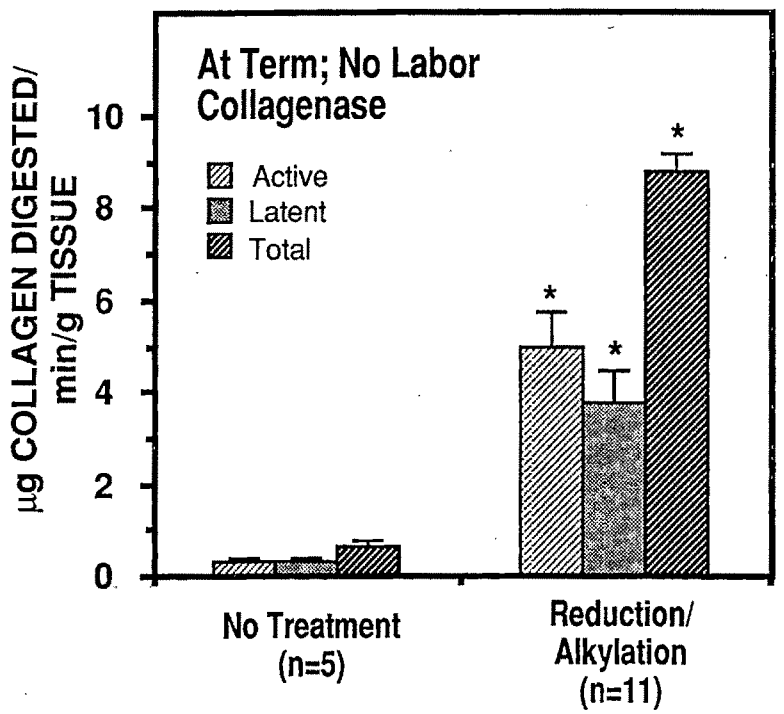

Fig. 1. Active, latent, and total collagenase in human placenta at term (37 to 42 weeks), not in labor (mean ± SEM). There is a twelvefold to seventeenfold increase in collagenase activity after inactivation of tissue inhibitor of metalloproteinase by reduction with dithiothreitol and alkylation with iodoacetamide; *n* refers to numbers of placentas tested. *Asterisk* denotes $p < 0.001$ for the difference between active, latent, and total collagenase levels before and after reduction-alkylation.

immediately at delivery according to a protocol approved by the local human research committee at the University of Miami. Tissue was taken from those cesarean sections performed at term (37 to 42 weeks) for standard indications from two groups of women with normal gestation. One group was in labor with the cervix dilated 4 to 8 cm and the other group was not in labor and the cervix was closed (0 to 2 cm). Approximately 10 gm of tissue was excised across the fetal and maternal sides of the placenta. The membranes and major vessels were removed. The tissue specimens were washed in ice-cold normal saline solution, frozen at −20° C overnight, and stored at −70° C. Specimens were thawed at room temperature immediately before extraction of collagenase for assay.

Preparation of collagenase substrate. Acid-soluble collagen was purified from the skins of adult female rats (Sprague Dawley, Charles River Breeding Laboratories, Wilmington, Mass., 225 to 275 gm) as described.[11] Briefly, collagen was extracted in 0.5 mol/L acetic acid at 4° C and precipitated by 1.7 mol/L sodium chloride. After two cycles of redissolving and reprecipitating, the precipitate was dissolved (1.5 to 2.0 mg/ml) in buffered 2 mol/L urea and dialyzed. This product is referred to as intact collagen. Intact collagen was then acetylated with tritiated acetic anhydride.[12] The telopeptide ends of this labeled collagen were removed by pepsin digestion.[13] Labeled telopeptide-free collagen was purified and sodium dodecyl sulfate–gel electrophoresis was used to evaluate the completeness of the pepsinization as described.[11] The final product contained approximately 6.4×10^6 cpm/mg collagen.

Preparation of collagenase

Serum samples. Blood samples were obtained from mothers and umbilical cords immediately at delivery. Samples were collected in plain tubes and allowed to clot at room temperature for 30 minutes. They were then chilled and centrifuged for 15 minutes at 1500 rpm (750 *g*) at 4° C. The serum was withdrawn to within 1 cm of the clot to avoid contamination with leukocytes and frozen at −20° C until assayed. Samples were thawed at room temperature immediately before processing for collagenase assay. The α_2-macroglobulin was inactivated by dialyzing serum versus 3 mol/L potassium thiocyanate in 50 mmol/L Tris–hydrochloric acid and 10 mmol/L calcium chloride, pH 7.5, for 6 hours at 4° C and then against 100 volumes of assay buffer for 18 hours.[14] The assay buffer consisted of 50 mmol/L Tris–hydrochloric acid, 200 mmol/L sodium chloride, 10 mmol/L calcium chloride, 0.05% Brij 35, and 0.02% sodium azide, all adjusted to pH 7.5.

Table IV. Status at second return visit 1 Month after therapy for bacterial vaginosis as a Function of qualifiers of cure at first return visit 4 to 7 days after treatment

Status at first return visit	*n**	*Status at second return visit*			
				Examination normal except	
		Normal†	*Recurrent bacterial vaginosis*	*Vaginal pH >4.5*	*Discharge of bacterial vaginosis*
Unqualified cure	13	8 (61.5%)	1 (7.7%)	4 (30.8%)	0
Cure with pH >4.5	27	18 (66.7%)	3 (11.1%)	5 (18.5%)	1 (3.7%)
Cure with positive potassium hydroxide sniff test	1	1	0	0	0
Cure with candidiasis	2	0	1	1	0
TOTAL	43	27 (62.8%)	5 (11.6%)	10 (23.3%)	1 (2.3%)

*Only those patients for whom second return visit data are available are included.
†No criteria for diagnosis of bacterial vaginosis present.

Table V. Correlation of laboratory parameters with presence or absence of bacterial vaginosis by clinical criteria relative to intravaginal clindamycin or placebo treatment, including visits after blinded and open-label regimens

Parameter	*Result*	*Entry visit: Bacterial vaginosis*		*4-7 days after completion of treatment: Bacterial vaginosis*		*1 mo after completing treatment: Bacterial vaginosis*		*Cumulative: Bacterial vaginosis*	
		Present	*Absent*	*Present*	*Absent*	*Present*	*Absent*	*Present*	*Absent*
Gram stain	Consistent with Bacterial vaginosis	67(100%)*	—	14(82.4%)	4(6.7%)	9(100%)	2(5.3%)	23(88.5%)	6(6.1%)
	Indetermiante	0	—	3(17.6%)	46(76.7%)	0	11(28.9%)	3(11.5%)	57(58.2%)
	Normal	0	—	0	10(16.7%)	0	25(65.8%)	0	35(35.7%)
Proline aminopeptidase activity	Positive	27(79.4%)	—	5(100%)	9(34.6%)	6(100%)	5(23.8%)	38(84.4%)	14(29.8%)
	Negative	7(20.6%)	—	0	17(65.4%)	0	16(76.2%)	7(15.6%)	33(70.2%)

	Absent	31(46.3%)	—	8(47.1%)	59(100%)	6(60.0%)	37(97.4%)	45(47.9%)	96(99.0%)

*All patients entering the study were required to have a vaginal Gram stain consistent with bacterial vaginosis. Data in this category are not entered in the cumulative Gram stain data.

teria (6 of 15, 40.0%). Odor and discharge symptoms were resolved in 34 of 47 (72.3%) and 6 of 15 (40.0%), respectively ($p > 0.05$). At the second return visit all symptoms were resolved in 27 of 33 (81.8%) patients with durable cure and in 3 of 5 with recurrent bacterial vaginosis; odor and discharge were resolved in 29 of 33 (87.9%) and 3 of 5, respectively. Similarly, no significant association was found between any of the objective diagnostic criteria and a given symptom.

Among the 47 patients who met criteria for cure at 4 to 7 days after blinded therapy, 28 (59.6%) had persistent elevation of vaginal pH >4.5, one (2.1%) retained a positive sniff test, and none had persistence of discharge consistent with bacterial vaginosis. Table IV shows the relationships between status at the first and second return visits for patients who were initially cured and attended both visits. Recurrence of bacterial vaginosis was equally likely among any of the cure groups as classified at the first return visit.

There were four patients declared cured by our criteria at the first return visit whose vaginal Gram stain remained consistent with bacterial vaginosis; at the second return visit two of them were unqualified cures and two had recurrent disease. Among nine patients who retained positive proline aminopeptidase activity despite clinical cure at the first return visit, at the second return visit seven of eight showed durable cure; four were completely normal, and one each had vaginal candidiasis, pH >4.5, and candidiasis plus pH >4.5.

Durability of cure relative to exposure to male sexual secretions was also examined. Among five patients cured by blinded treatment at the first return visit who

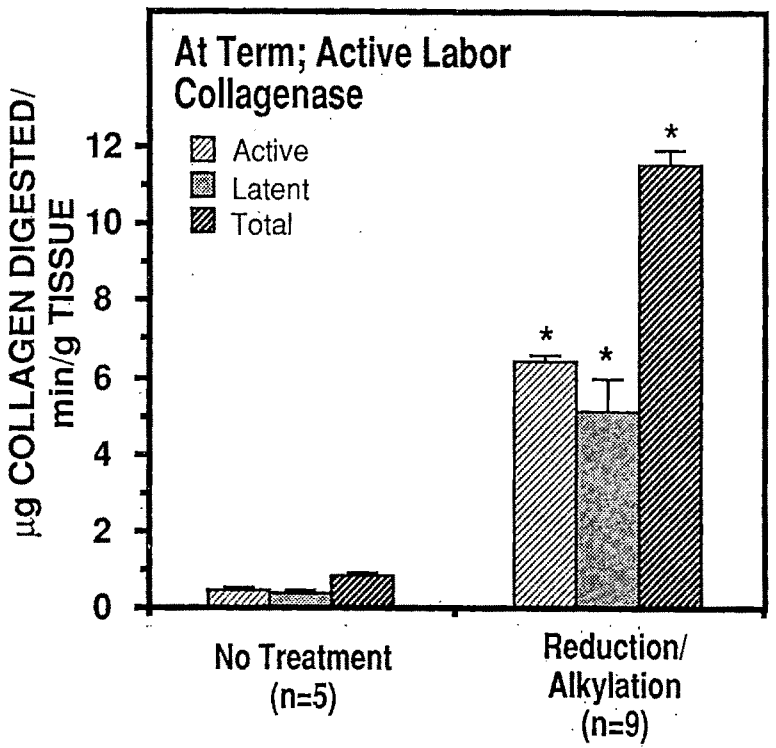

Fig. 2. Active, latent, and total collagenase in human placenta at term (37 to 42 weeks), in active labor (mean ± SEM). There is a thirteenfold to fourteenfold increase in collagenase activity after inactivation of tissue inhibitor of metalloproteinase by reduction with dithiothreitol and alkylation with iodoacetamide; *n* refers to number of placentas tested. *Asterisk* denotes $p < 0.001$ for the difference between active, latent, and total collagenase levels before and after reduction-alkylation.

Placental samples. Collagenase was extracted from placental specimens according to the method of Sellers and Woessner.[15] First the tissue was homogenized in 10 volumes 0.1% Triton X-100 and 10 mmol/L calcium chloride, then the residual tissue was further extracted in 100 mmol/L calcium chloride in 50 mmol/L Tris–hydrochloric acid buffer, pH 7.5, at 60° C for 4 minutes to yield a heat extract. The Triton extract and the heat extract were then dialyzed against assay buffer overnight. Aliquots were removed for enzyme assay and the remainder was stored at −20° C.

Collagenase assay method. Collagenase assay was done according to the method of Dean and Woessner.[11] Enzyme samples (12.5 μl serum, 20 to 100 μl placental extract) were incubated in polypropylene tubes with 35 μg of [^{3}H]telopeptide-free collagen. Aminophenylmercuric acetate (0.5 mmol/L) was added to activate latent collagenase and 1,10-phenanthroline (1 mmol/L) was added for blanks. The total volume was adjusted to 110 μl with assay buffer. Incubation was for 20 hours at 30° C. The reaction was stopped by adding ethylenediaminetetraacetic acid to a final concentration of 40 mmol/L. Acid-soluble intact collagen (200 μg) was added as carrier with 35 μg chymotrypsin and 35 μg trypsin, and the mixture was incubated at 30° C for 90 minutes to digest the products of collagenase action. The undigested [^{3}H]telopeptide-free collagen was precipitated by an equal volume of ice-cold 20% trichloroacetic acid and collected on Millipore AP15-025-00 glass fiber filters (Millipore Corp., Bedford, Mass.), placed into 10 ml Aquasol scintillation fluid, and counted in a Packard Tri-Carb scintillation spectrometer (Packard Instrument Co., Downers Grove, Ill.) (58% efficiency). The percent digestion is calculated as [(Blank − Digest)Blank] × 100. One unit of collagenase is defined as 1 μg [^{3}H]telopeptide-free collagen digested per minute at 30° C. Tissue inhibitor of metalloproteinase was inactivated by reduction of placental extracts with 2 mmol/L dithiothreitol followed by alkylation with 5 mmol/L iodoacetamide.[9, 16] After dialysis against assay buffer, samples were assayed for collagenase as described.

Gel-filtration chromatography. Samples of enzyme extracts (10 ml) were applied to a 1 × 110 cm column of Ultragel ACA-34 equilibrated with assay buffer containing 1 mol sodium chloride. Fractions of 10 ml were collected and dialyzed against assay buffer. Fractions were assayed with and without aminophenylmercuric acetate to determine the positions of latent and active collagenase, respectively. Molecular weights were estimated on the basis of protein markers chromatographed under identical conditions.

had recurrent bacterial vaginosis at the second return visit, all had been exposed (had had intercourse without condoms); 19 of 38 (50%) patients with durable cure had been exposed ($p = 0.06$). When participants in the open-label treatment protocol are included, 6 of 8 (75.0%) with recurrent disease and 21 of 40 (52.5%) with durable cure had been exposed ($p = 0.44$).

Relationships between the laboratory tests we evaluated and our clinical criteria for diagnosis of bacterial vaginosis were examined at each visit and are shown in Table V. The total numbers at each return visit exceed those at the entry visit in this table because all evaluations after blinded, open-label, and placebo therapy are included.

Comment

Although abnormal discharge (91.0%) and vaginal odor (73.1%) were the most common presenting symptoms, two thirds of our patients had other symptoms. Almost half (44.8%) of our patients with pure bacterial vaginosis presented with complaints of vulvovaginal irritation and there was objective evidence of it in 29.9%. Amsel et al.[7] found irritative symptoms in 15.9% of their patients, and Taylor et al.[16] found signs of vaginal inflammatory change in 20%. Despite the generally noninflammatory nature of this process, practitioners should not be dissuaded from the diagnosis by such symptoms or signs. Although one study[14] has suggested a causal relationship between bacterial vaginosis and abnormal uterine bleeding, Eschenbach et al.[13] did not identify a correlation between them; the prevalence of abnormal bleeding was very low (4.5%) among our patients with pure bacterial vaginosis. Thus not only are up to half of the patients with bacterial vaginosis reported in the literature asymptomatic, but in our symptomatic study population there is a wide range of complaints (Table II), and symptomatic response to therapy has inadequate correlation with outcome by objective criteria. Consequently, we advise clinicians to use a "test of cure" examination.

We emphasize that at study entry over 10% of our patients were described to have a vaginal discharge that was either physiologic or absent. Because bacterial vaginosis is often asymptomatic and because abnormal discharge is the only one of the four criteria for diagnosis that can be assessed simply during the examination, clinicians may use the presence of an abnormal vaginal discharge as the "trigger" to consider the diagnosis of bacterial vaginosis; this approach will result in missing as many as one in 10 cases.

A significantly higher frequency of adnexal tenderness (4%) and a diagnosis of pelvic inflammatory disease (3%) has been described for patients with bacterial vaginosis.[13] We found uterine or adnexal tenderness or both, in 10 of our 67 (14.9%) patients with pure bacterial vaginosis, three of whom had had hysterectomy; none of these patients was considered to have pelvic inflammatory disease, which would have excluded them from the study. Among those with the uterus in place who returned for follow-up, tenderness had resolved in four of four immediately after curative treatment for bacterial vaginosis and in one of two therapeutic failures. These data suggest that the association between bacterial vaginosis and upper genital tract infection should be pursued.

Other investigators[13] have noted that elevation of vaginal pH is the most sensitive but least specific of the criteria currently used for diagnosis of bacterial vaginosis. In this study the high frequency (59.6%) of persistent vaginal pH >4.5 4 to 7 days after otherwise curative clindamycin treatment negates its diagnostic usefulness in this setting. In addition, increased vaginal pH after otherwise curative treatment did not predict recurrence of bacterial vaginosis within the time frame of this study (Table IV). This finding greatly reduces the likelihood that the original pathogenic event in bacterial vaginosis is relative vaginal alkalinity per se. One month after treatment vaginal pH>4.5 was found in 10 of 38 (26.3%) patients who remained free of bacterial vaginosis, although only five of those 10 were from the group with elevated pH at the first return visit. Whether such lability of vaginal pH is peculiar to a population at persistent risk for bacterial vaginosis cannot be determined from our study.

The frequencies of any contraceptive method other than use of an intrauterine device or any sexual practices, specifically oral-vaginal or penile-anal sex, among our patients with bacterial vaginosis are similar to our general patient population. Most patients were in excellent general health. Clearly, neither cervical mucus nor menstrual flow is required for persistence of bacterial vaginosis since 13.4% of our patients had had hysterectomy.

Our data do not strongly suggest a sexually transmitted cause for bacterial vaginosis. Among our patients we found a relatively low mean number of admitted sexual partners during the preceding 12 months (1.4), a low frequency of genital symptoms in male sexual partners (11.9%), a low rate of recurrent bacterial vaginosis in the absence of treatment of male sexual partners, and no demonstrable difference in recurrence rates as a function of exposure to male genital secretions. Clearly, however, these findings do not conclusively refute sexual transmission, and it should be noted that 71.6% of our patients were unmarried and therefore less likely to be monogamous, and 40.3% gave a history of sexually transmitted disease. It remains possible that our patients had acquired the disease from a remote sexual partner, and that larger numbers of patients may have shown a significantly more frequent

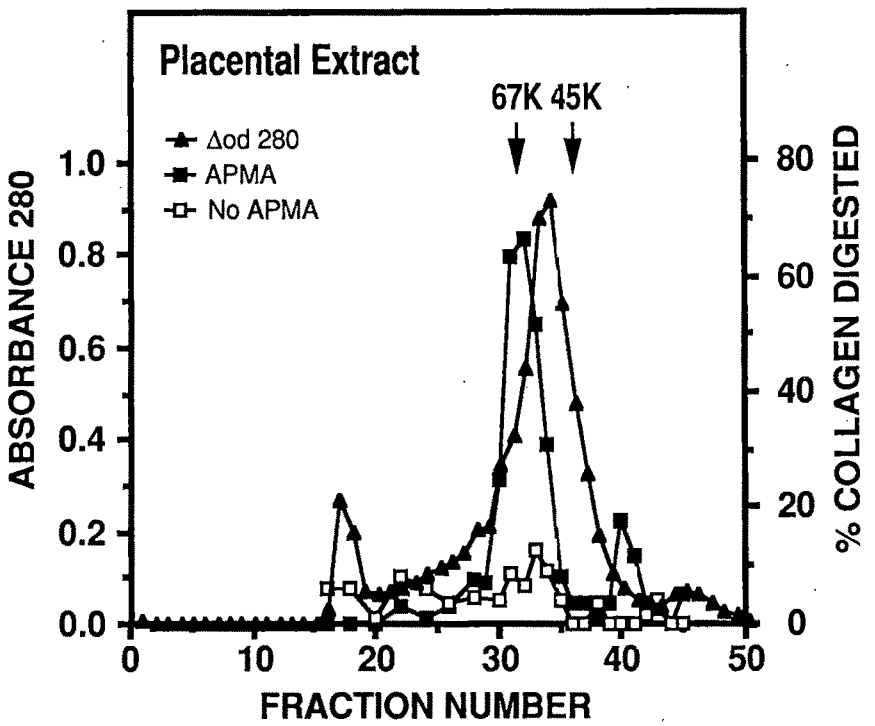

Fig. 3. Gel-filtration chromatography of human placental collagenase (active labor). Heat-extracted collagenase (10 ml) was subjected to gel-filtration chromatography as described in Material and methods section. The absorbance of 280 nm was determined after chromatography. Fractions were dialyzed against assay buffer, and 100 μl aliquots were assayed for collagenase without aminophenylmercuric acetate *(APMA)* (active collagenase) and in the presence of 0.5 mmol/L aminophenylmercuric acetate (latent collagenase). *67 K* and *45 K* refer to elution position of bovine serum albumin and ovalbumin, respectively.

Results

Recovery of collagenase in placental extracts. Collagenase is present in an active form and a latent form. Assay of placental extracts in the absence of aminophenylmercuric acetate detects the active enzyme. Addition of aminophenylmercuric acetate detects the total free (unbound) enzyme present in tissue extracts. The difference between total and active enzyme yields latent enzyme (i.e., that enzyme that cannot be assayed until it is activated). Both the Triton and the heat extracts contained significant amounts of collagenase (approximately one third and two thirds, respectively). Although each fraction was assayed separately, there was no significant change in distribution of collagenase levels in the different extracts before and after labor. Therefore all the data reported are the summation of the two extracts.

Collagenase in human placenta. Assay of dialyzed placental extracts revealed the presence of low collagenase activity. Placentas at term showed mean collagenase levels for active, latent, and total enzyme at 0.29 ± 0.11, 0.32 ± 0.05, and 0.64 ± 0.13 U/gm tissue, respectively (one unit = 1 μg collagen digested per minute at 30° C, mean ± SEM, $n = 5$) (Fig. 1). After spontaneous labor, collagenase levels increased to 0.45 ± 0.11, 0.39 ± 0.1, and 0.84 ± 0.06 U/gm for active, latent, and total collagenase, respectively ($n = 5$) (Fig. 2). The differences were not statistically significant. This low level of collagenase could reflect either a low enzyme concentration, excess inhibitor(s), or both. This issue was resolved by gel-filtration chromatography. The total enzyme activity in crude extracts was greatly increased after chromatography. This indicates that the low levels of collagenase activity were primarily the result of the presence of excess inhibitor(s) that were separated by the chromatography. Presumably the active enzyme and the latent enzyme, after activation by aminophenylmercuric acetate, become bound to inhibitors during the 20-hour assay. The two known inhibitors of collagenase are α_2-macroglobulin and tissue inhibitor of metalloproteinase. Therefore attempts were made to inactivate α_2-macroglobulin by treatment of placental extracts with potassium thiocyanate and to inactivate tissue inhibitor of metalloproteinase by reduction with dithiothreitol and alkylation with iodoacetamide as described in Methods. Inactivation of α_2-macroglobulin did not increase active, latent, or total collagenase in placental extracts (data not

recurrence rate with exposure to semen, as was suggested by the trend seen among patients in the blinded portion of our study.

Our data support the specificity of curved rods (*Mobiluncus* spp. morphotypes) for bacterial vaginosis.[6] In the blinded treatment protocol these organisms were absent among patients cured of bacterial vaginosis by our criteria in 46 of 46 patients at the first return visit and in 36 of 37 at the late visit, and for all data points had an overall specificity in diagnosis of bacterial vaginosis of 99.0% (96 of 97). Among 94 visits of patients with bacterial vaginosis, we identified these organisms in 49 (52.1%). These findings also confirm the susceptibility of *Mobiluncus* spp. to clindamycin as previously reported,[6] and establish the efficacy of topical local treatment.

Using all data points ($N = 92$), we found proline aminopeptidase activity in vaginal fluid to have a sensitivity of 84.4% and specificity of 70.2%. After treatment sensitivity of proline aminopeptidase was 100% (Table V). When this test remains positive after otherwise curative treatment, it does not seem to predict recurrence. However, proline aminopeptidase activity is more sensitive, specific, and practical than gas-liquid chromatographic analysis of vaginal secretions and may emerge as the preferred laboratory test for diagnosis. It is of interest that 10 of 14 (71.4%) false-positive tests occurred in patients with vaginal pH >4.5. We did not find a correlation between the presence of proline aminopeptidase and *Mobiluncus* spp. morphotypes.

We concur with Spiegel et al.[2] with regard to the utility of Gram stain of vaginal fluid in diagnosis of bacterial vaginosis. All of our 67 patients with pure bacterial vaginosis by our clinical criteria at the time of enrollment had confirmatory vaginal Gram stain findings. Although usefulness of Gram stain criteria immediately after therapy was limited by a high frequency of indeterminate results, 1 month after treatment the frequency of indeterminate results decreased. Restoration of a lactobacillus-dominated flora after treatment can be documented by Gram stain classified as normal (Table V). Overall, after treatment the accuracy of a positive result was 79.3% (23 of 29) and of a negative result 100% (35 of 35). It would be useful to compare vaginal Gram stains after systemic metronidazole therapy.

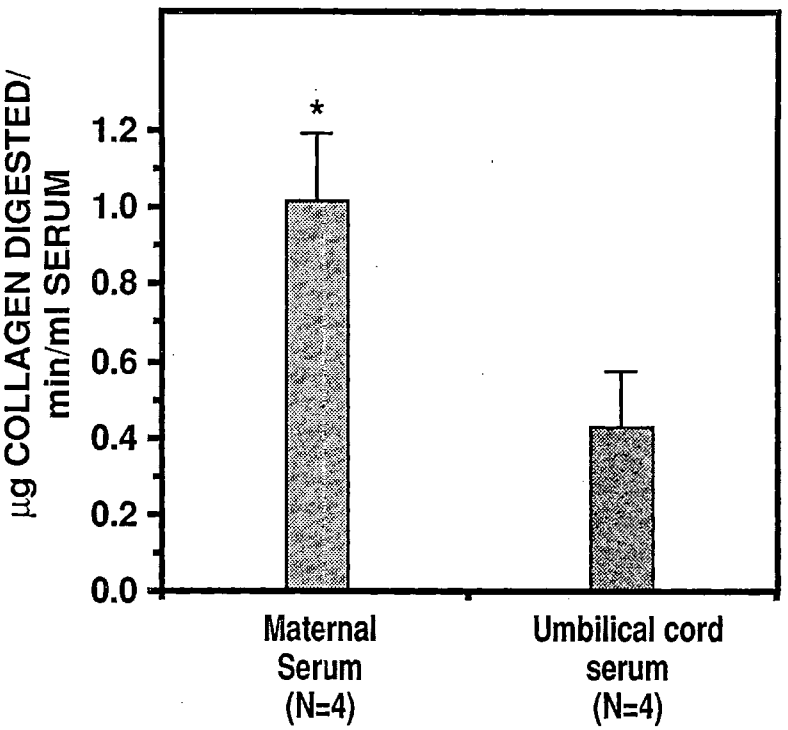

Fig. 4. Distribution of serum collagenase in maternal and neonatal compartments. Collagenase activity was measured in serum after inactivation of α_2-macroglobulin by potassium thiocyanate on paired sera from maternal veins and umbilical cords immediately at delivery (n = four pairs). Maternal serum collagenase levels are higher than umbilical cord serum levels ($p < 0.05$).

shown). Inactivation of tissue inhibitor of metalloproteinase, however, resulted in a marked increase in active, latent, and total collagenase (Figs. 1 and 2). The activity of collagenase recovered was approximately equal to the activity recovered from gel-filtration chromatography. On the basis of this recovery, all placental extracts were reduced and alkylated, dialyzed, and assayed for collagenase. As shown Figs. 1 and 2, placentas at term (in presence or absence of labor) showed a twelvefold to seventeenfold increase in collagenase activity after reduction and alkylation. After the onset of labor there was a statistically significant increase in total enzyme (from 8.76 ± 0.41 to 11.52 ± 0.44 U/gm, $p < 0.01$).

Chromatography of placental collagenase. Extracts of collagenase were chromatographed on an Ultrogel AcA-34 column (LKB Instruments, Rockville, Md.) as described in Methods. Dialyzed fractions were assayed for collagenase in the presence or absence of aminophenylmercuric acetate. The latent form of collagenase had an apparent relative molecular mass of 65,000 d (Fig. 3). The apparent relative molecular mass of spontaneously active enzyme was slightly lower than that of the latent form at 60,000 d.

Maternal-fetal serum collagenase. Fig. 4 represents collagenase activity in maternal and umbilical cord serum taken simultaneously at delivery. Umbilical cord serum levels were lower than those in maternal circulation.

Comment

This study reports the detection of collagenase in human placenta at term and on optimization of detection of the extracted enzyme. The increased recovery of collagenase activity after gel-filtration chromatography was found to be caused by the presence of excess tissue inhibitor of metalloproteinase. Tissue inhibitor of metalloproteinase is the major inhibitor of collagenase and other metalloproteinases in the extracellular matrix of many human tissues. It inhibits collagenase in a 1:1 stoichiometric ratio. It contains disulfide bridges that are essential for activity. Free tissue inhibitor of metalloproteinase is completely inactivated by reduction and alkylation as described under Methods (for review see Stricklin and Welgus[17] and Stricklin[18]). Our results indicate that tissue inhibitor of metalloproteinase is also the major collagenase inhibitor in human placenta. Since potassium thiocyanate treatment of placental extracts did not increase collagenase activity, it is unlikely that α_2-macroglobulin plays a significant role in controlling collagenolysis in the extracellular matrix of human placenta. This is in agreement with the fact that α_2-macroglobulin is mainly present in the circulation and its large size (apparent relative molecular

The relationship of cocaine use to syphilis and human immunodeficiency virus infections among inner city parturient women

Howard L. Minkoff, MD,[a] Sandra McCalla, MD,[a] Isaac Delke, MD,[a] Roy Stevens, MD,[d] Martin Salwen, MD,[c] and Joseph Feldman, DrPH[b]

Brooklyn and Albany, New York

To study the relationship of cocaine use to syphilis and human immunodeficiency virus infections a blinded urine and serum survey was performed among parturient women at an inner city hospital. Discarded urine samples of 1206 parturient women were saved and given code numbers that were also assigned to data sheets containing nonidentifying information, including prenatal care status and syphilis serologic results. In the latter part of the study blood remaining after syphilis serologic tests were performed (n = 480) were tested for human immunodeficiency virus antibodies. Overall 12.9% of urine samples had cocaine derivatives, 1.4% opiates, 1.5% marijuana, 0.0% benzodiazepine, and 0.3% methadone. The prevalence of positive rapid plasma reagin tests was 18.7% among patients with positive urine toxicologic tests for cocaine and 2.41% for patients wtih negative urine tests (odds ratio = 9.3, 95% confidence interval 5.2 to 16.5, $p < 0.001$). Fluorescent treponemal antibodies were also significantly more frequent among patients with positive urine samples. Four of 53 (7.6%) patients with positive urine toxicologic screens were human immunodeficiency virus antibody positive compared with six of 427 (1.4%) women with negative screens (odds ratio = 5.7, 95% confidence interval = 1.4 to 21.5, $p = 0.019$). Cocaine patients with positive cocaine screens and with syphilis or human immunodeficiency virus had prenatal care in 6 of 21 (28.6%) and 0 of 4 (0%) cases, respectively, while patients with negative cocaine screens and syphilis or human immunodeficiency virus had prenatal care in 13 of 18 (72.2%) and 5 of 6 (83.3%) cases, respectively ($p = 0.010$ and $p = 0.048$). Cocaine use appears to be associated with both the acquisition of human immunodeficiency virus and syphilis and the failure of infected individuals to utilize prenatal services. (Am J Obstet Gynecol 1990;163:521-6.)

Key words: Cocaine, syphilis, human immunodeficiency virus, prenatal care

The National Institute on Drug Abuse has estimated that in 1986 3 million people in the United States abused cocaine regularly.[1] Use by pregnant women, which can have serious consequences for both mother and child, has been reported to be common in inner city communities.[2] As cocaine use has become epidemic among indigent pregnant women, acquired immunodeficiency syndrome and syphilis have been spreading into the same population. The prevalence of human immunodeficiency virus (HIV) infection among pregnant women in New York City is 1.3% with even higher rates reported from the Bronx (1.9%), Newark (4.3%), and Miami (4.2%).[3, 4] Syphilis rates in endemic communities have increased 70% to 130% between 1986 and 1987.[5] The incidence of congenital syphilis has also risen dramatically, particularly in endemic areas such as Florida, Texas, California, and New York City.[6] The population that is disproportionately infected by both HIV and syphilis is urban, poor, minority women.

The occurrence of high rates of cocaine use and high rates of HIV and syphilis in the same areas is undoubtedly more than coincidence. The fact that shared needles can lead to HIV transmission, for example, is well documented. Intravenous use of cocaine has been reported to significantly increase the risk of HIV infection among intravenous drug users,[7] and there is anecdotal evidence that the use of nonparenteral forms of cocaine can contribute to the sexual acquisition of HIV and other sexually transmitted diseases.[8]

To date, published studies of the relationship of cocaine to HIV and syphilis have relied on patient histories elicited from specific populations (e.g., prostitutes) and are therefore limited in characterizing associations beyond the selected group, and none of these studies examined pregnant women.[8, 9] Since HIV and syphilis, as well as cocaine, have potentially serious consequences for the health of women and children in the

mass 725,000 d) will hinder its access to the extracellular matrix.[19, 20]

The amount of collagenase recovered from first (Triton) extract of the placenta represents two thirds of the total enzyme present. The remaining one third is recovered in the second (heat) extract. These results are similar to those found in human cervix, suggesting a functional similarity in enzyme distribution between the two organs.[10] Collagenase is produced by stromal cells (e.g., fibroblasts, smooth muscle cells) in a latent form (procollagenase) that is inactive and has low affinity for collagen substrate. The same cell that produces procollagenase also coordinately produces stromelysin, which activates procollagenase.[21] Active collagenase has a high affinity for fibrillar collagen and results in cleavage of the triple helix of collagen (for review on collagenase see Stricklin and Hibbs[22]). The presence of excess tissue inhibitor of metalloproteinase in human placenta, which inhibits active collagenase, suggests that collagen turnover in the extracellular matrix is well controlled and possibly highly localized at the microenvironment of active remodeling of collagen. This is in agreement with the finding that mouse trophoblasts in culture digest only the extracellular matrix immediately beneath the cells, with no evidence of digestion of the matrix beyond the periphery of the trophoblast outgrowth.[23] This biologic property of the trophoblast may play a significant role in implantation and attachment of the placenta to the myometrium without damage to remote areas.

This study demonstrates that human placenta at term is rich in collagenase and contains more enzyme than maternal serum. Assuming the wet weight of placenta at term to be 500 gm, it would contain 2480 and 1865 U of active and latent collagenase, respectively. These levels are 1.6- to 3.6-fold higher than those in the total maternal circulation.[9] Therefore it is possible that serum collagenase may originate from the placenta. This possibility is considered highly unlikely for the following reasons: (1) Active collagenase in placenta has a high affinity for fibrillar collagen substrate, which is abundant in the extracellular matrix. Assuming the presence of a loosely bound pool of active collagenase, the presence of excess tissue inhibitor of metalloproteinase makes it unlikely that a free active collagenase will find its way to the circulation. (2) Serum collagenase levels in pregnancy do not significantly differ from those in nonpregnant women. If placenta contributes to serum collagenase, higher levels of serum collagenase are expected in pregnancy than those encountered in nonpregnant state. (3) Serum collagenase levels are higher 1 day post partum in the absence of placenta than those immediately at delivery. (4) The presence of lower umbilical cord blood collagenase levels than those in maternal circulation is in agreement with this conclusion; although by itself it is not conclusive evidence because human chorionic gonadotropin for instance, which is produced by the placenta, crosses mainly to the mother and not to the fetus, resulting in lower umbilical cord blood levels.[24]

We have previously shown that the onset of labor leads to an increase in collagenase in uterine cervix and in the circulation in women at term. In this study a significant increase in total placental collagenase in labor was also shown. Hormonal signals that lead to the onset of labor also lead to an increase in collagenase production. Studies of hormonal regulation of collagenase production by human placenta therefore may be of value in understanding the mechanisms of implantation and parturition.

We thank Jane Wishart and Mark Lepik for preparing the figures.

inner city, a blinded urine and serum survey was conducted to more fully define the association between cocaine use and HIV and syphilis in pregnancy. An attempt was also made to relate the use of cocaine to the utilization of prenatal care services particularly by women infected with HIV and syphilis.

Material and methods

Patients. Between Oct. 18, 1988 and March 1, 1989, 1439 women giving birth at a municipal hospital in New York City had urine samples, which otherwise would have been discarded, saved and given code numbers as part of a prospective study of illicit drug use and pregnancy outcomes. All urine samples were collected within 18 hours of admission. Selection was based on admission during shifts when a research assistant was available to collect urine specimens. These shifts varied throughout the day and throughout the week. Although the selection of shifts was not strictly random, the random nature of delivery dates should have produced a random sample. A comparison of drug use between women delivered on weekends and on weekdays revealed no differences in frequency of drug use. In the latter part of the study blood specimens were saved after syphilis serologic tests were performed and were given code numbers matched to urine and data sets. These 480 coded blood samples were subsequently tested for HIV antibodies.

Researchers systematically retrieved information from delivery logs and patient records on days subsequent to admission (before testing of urine and blood). If the chart abstractor noted missing data, the clinician was asked to complete the record. Data sheets did not contain identifiers. Data included drug use history, history of prenatal care, syphilis serologic results, and risk factors for HIV. This information was given the same code number as the urine. In some instances patients either left the hospital before data could be collected (e.g., delivery on days before research assistant off days, $n = 199$) or had neither serologic nor HIV results available on their chart ($n = 34$). Data were available on 1206 patients. Urine toxicologic studies were also run on the patients without complete data sheets to assess potential ascertainment bias. The data collected permitted a cross-sectional comparison between drug use and the presence of syphilis and HIV infection. The study set for this report includes the 1206 patients with both urine and data sets. Of these 726 had syphilis serologic results available but not HIV results (as noted, HIV serologic results were only performed in the latter part of the study), 461 had syphilis and HIV serologic results, and 19 had HIV but not syphilis serologic results (syphilis serologic results were collected from patient records, results were missing in 19 cases).

Data analyses. Confidence intervals and mid p values for the odds ratio estimates of HIV and syphilis for an exposure to cocaine, etc., were based on exact methods.[10-12] The p values were two-tailed. In this approach confidence limits are based on hypergeometric probabilities conditional on fixed margins, which correspond to Fisher's exact test of significance, Exact methods are most useful when sample sizes are small or when disease prevalence is relatively infrequent as in the present study. The actual computations were performed with a computer program developed by Foster.[13]

Laboratory

Toxicology. Urine screening for illicit drugs was performed with a homogeneous enzyme-multiplied immunoassay technique (Syva Emit d.a.u.) for cannabinoid, cocaine, and opiate assays[14-21] (details available on request).

Serologic tests for syphilis. Serum specimens were examined in qualitative rapid plasma reagin card tests. Samples found nonreactive with rapid plasma reagin were recorded as negative and not examined further. Reactive specimens underwent quantitative tests and were also tested in the confirmatory fluorescent treponemal antibody–absorption test. Samples that were rapid plasma reagin reactive, fluorescent treponemal antibody–absorption nonreactive were recorded as biologic false-positive results; those reactive in both tests were recorded as positive.

Tests for HIV-1 antibody. Specimens were examined in a standard HIV-1 enzyme-linked immunosorbent assay (ELISA) antibody procedure (Dupont) followed, where indicated, by a Western blot test. Test results were reported as negative (ELISA nonreactive), inconclusive (blot test nonreactive or equivocal), or positive (blot test reactive). A reactive blot included, as a minimum, virus-specific bands at 160/120 or 41 and 31 or 24 kd.

This study was approved by the Institutional Review Board of State University of New York Health Science Center at Brooklyn and the New York City Health and Hospital Corporation.

Results

A description of the population studied is provided in Table I. The frequency of positive results of urine toxicologic screens among the 1206 study patients was 12.9% for cocaine (90.3% of which were positive only for cocaine), 1.4% for opiates, 1.5% for marijuana, 0.0% for benzodiazepine, and 0.33% for methadone. The frequency of positive results of urine cocaine toxicologic screens among patients with urine collected but without data sheets was 12.6%, which did not differ significantly from results of patients with data sheets. The prevalence of positive rapid plasma reagin test results was 18.7% (28 of 150) for patients with positive urine toxicologic screens for cocaine and 2.4% (25 of 1037) for patients with negative urine test results for

Preeclampsia in diabetic pregnancies

Peter R. Garner, MD, Mary E. D'Alton, MD, Denis K. Dudley, MD, Pierre Huard, MD, and Michael Hardie, MD

Ottawa, Ontario, Canada

Diabetic pregnancies complicated by preeclampsia are of concern because of poor perinatal outcome. However, with improved maternal and fetal surveillance the impact of preeclampsia in diabetic pregnancies is declining. This prospective controlled study compared the incidence of preeclampsia and maternal-fetal outcome in 334 diabetic pregnancies and 16,534 nondiabetic pregnancies. The incidence of preeclampsia was 9.9% (33/334) in diabetic pregnancies compared with 4.3% (716/16,534) in nondiabetic controls. The incidence of preeclampsia rose with increasing severity of diabetes by White classification, but was still 8.9% after exclusion of diabetic patients with nephropathy or chronic hypertension. The perinatal mortality rate per 1000 births was 60 for preeclamptic diabetic patients compared with 3.3 for normotensive diabetic patients. Parity, maternal age, and blood glucose control were similar in preeclamptic diabetic patients compared with normotensive diabetic patients. We conclude that preeclampsia is twice as common in diabetic pregnancies compared with normal controls. (Am J Obstet Gynecol 1990;163:505-8.)

Key words: Diabetes mellitus, preeclampsia, pregnancy, White classification

One of the first suggestions that the incidence of preeclampsia was increased in diabetic pregnancies originated from the Joslin Clinic records, which indicated a 50% incidence before 1938.[1] Subsequent reviews from both North American and British centers from 1953 to 1963 showed an average incidence of preeclampsia in diabetic pregnancies of 25%.[2] However, there were marked variations between centers (8% to 48%), which reflected differences in diagnostic criteria and management. In 1965, Pedersen[3] suggested a new classification for prediction of the outcome of pregnancies complicated by diabetes mellitus. This described four signs of poor prognosis in pregnancy (PBSP classification or Prognostically Bad Signs in Pregnancy), one of which was preeclampsia. This system complemented the White classification, which also attempted to predict perinatal outcome on the basis of age of onset, duration of diabetes, and other diabetic complications.[4] Use of the White classification suggested that the incidence of preeclampsia in diabetic pregnancies increased significantly with the severity of diabetes.

Since the introduction of these classifications, the course and outcome of diabetic pregnancies have greatly changed. As a result doubt has been expressed

cocaine (odds ratio = 9.3, 95% confidence interval = 5.2 to 16.5, $p = <0.001$) (Table II). Information on confirmatory fluorescent treponemal antibody–absorption test was available for 22 of the 28 patients with cocaine-positive results and positive rapid plasma reagin, and 22 of the 25 patients with cocaine-negative results and reactive rapid plasma reagin. Among patients with cocaine-positive results 21 of 22 (95.5%) had confirmation by fluorescent treponemal antibody–absorption test, while 18 of 22 (81.8%) positive rapid plasma reagin tests among patients with cocaine-negative results were confirmed. The odds ratio of a positive rapid plasma reagin test with a confirmatory positive fluorescent treponemal antibody–absorption test among cocaine users was 9.6 (21/144 vs. 18/1034), 95% confidence interval = 5.0 to 18.8, $p < 0.001$. There were no positive rapid plasma reagin tests among those with opiate metabolites in the urine.

HIV and urine results were available from 480 patients. Four of 53 (7.6%) patients with positive urine screens for cocaine were HIV antibody positive compared with 6 of 427 (1.4%) patients whose urine was negative for cocaine (odds ratio = 5.7, 95% confidence interval = 1.4 to 21.5, $p = 0.019$). None of the 10 HIV-positive patients had other drugs documented in the urine. Among the six patients with HIV-positive, cocaine-negative results one acknowledged intravenous drug use and two were from countries where HIV is endemic. Among the four patients with HIV-positive, cocaine-positive results one acknowledged intravenous drug use in the past. (Only 9 of 115 [7.8%] patients whose medical history included cocaine use noted that they took it parenterally, with the rest either smoking it [$n = 66$] or snorting it [$n = 40$]). Among nine of the 10 HIV-positive patients who had rapid plasma reagin tests, one had a positive result. This can be compared with 15 positive rapid plasma reagin tests among 458 HIV-negative patients (odds ratio = 3.7, 95% confidence interval 0.2 to 25.2, $p = 0.306$).

Among the 10 patients with HIV-positive results five had no prenatal care, four had care at the study institution, and one reported care elsewhere, which was undocumented. Among the 470 patients with HIV-negative results prenatal care status was recorded on the charts of 457. Sixty-eight (14.9%) had no care, 334 (73%) had care at the study site, and 55 (12.1%) had undocumented care elsewhere. None of the four patients with HIV-positive, cocaine-positive results had prenatal care, compared with five of six patients with HIV-positive, cocaine-negative results who had some care ($p = 0.048$) (Table III). Among patients with positive fluorescent treponemal antibody–absorption tests and known care status ($n = 39$), 20 (51.3%) had no care, 17 (43.6%) had care at the study hospital, and 2 (5.1%) had undocumented care elsewhere. Patients who had positive fluorescent treponemal antibody–absorption tests and cocaine-positive results had some prenatal care in six of 21 (28.6%) cases, while patients with positive fluorescent treponemal antibody–absorption tests and cocaine-negative results had prenatal care in 13 of 18 (72.2%) cases ($p = 0.010$) (Table II). Among patients with positive rapid plasma reagin tests who were not cared for at the study hospital ($n = 29$), 17 (58.6%) had been seen in an emergency room during the prenatal period.

Comment

We have found among a group of inner city parturient women that detection of cocaine derivatives in urine samples was significantly associated with positive rapid plasma reagin tests, fluorescent treponemal antibody–absorption antibodies, and HIV antibodies in maternal blood. Patients with syphilis or HIV infections, particulary those who used cocaine, often had received no prenatal care.

D,F,R	10	3	30.0
TOTAL	334	33	9.9

as to whether the incidence of preeclampsia in diabetic pregnancies is now higher than expected in nondiabetic pregnancies.[1,2] This prospective controlled trial was undertaken to assess whether the incidence of preeclampsia was greater in diabetic pregnancies as compared with nondiabetic controls, and if an increased incidence was shown, whether it was related to glycemic control, age, parity, duration of diabetes, or the presence of diabetic complications.

Material and methods

The patient population for the trial consisted of all pregnant diabetic women who attended the Ottawa Civic Hospital Maternal-Fetal Day Unit from January 1, 1979, to December 31, 1986. The control population comprised pregnant (nondiabetic) women delivered in the same hospital over the same period of time. Diagnosis of preeclampsia was made on the basis of the criteria of the Committee on Terminology of the American College of Obstetricians and Gynecologists (1972).[6] Blood pressure measurements were taken from the upper arm with the patient in the lateral position every 2 weeks from 28 to 36 weeks' gestation and weekly or twice weekly according to maternal and fetal monitoring needs from 36 weeks' gestation to delivery. Serial measurements of serum uric acid, creatinine, and blood urea nitrogen levels were performed every 2 weeks during the third trimester. Diagnosis of gestational diabetes was made on the basis of the National Diabetes Data Group criteria for gestational diabetes.[7]

Management of the diabetic pregnancies followed the guidelines suggested by the American College of Obstetricians and Gynecologists.[8] The principle of perinatal care was outpatient management while awaiting fetal pulmonary maturity. Hospital admissions were limited to obstetric indications, diabetic complications, and delivery. Evaluation of blood glucose control was accomplished by frequent fasting and postprandial levels measured 1 hour after breakfast, lunch, and dinner. Home glucose monitoring was accomplished by Chemstrip measurements (Bio-Dynamics, Indianapolis) two to four times daily supplemented by laboratory estimations of blood glucose levels. The mean glucose levels were determined on the basis of an average of 50 readings per patient. Goals for blood glucose control were fasting <100 mg/dl (<5.5 mmol/L) and <140 mg/dl (<8.0 mmol/L) postprandially. Patients with gestational diabetes were initially treated by diet alone according to the dietary recommendations of the American Diabetes Association.[9] Insulin supplementation was added if target blood glucose levels were not reached after 2 weeks of dietary control. Type I insulin-dependent diabetic patients were controlled with neutral protamine Hagedorn and regular insulin injection administered two or three times a day in addition to diet. Antepartum fetal monitoring consisted of nonstress testing weekly or more frequently if indicated from 34 weeks' gestation to delivery in the case of type I diabetes. After a nonreactive nonstress test further evaluation of fetal status was made by a biophysical profile. Fetal growth was assessed by serial ultrasonography every 2 to 3 weeks in the third trimester. Pregnancies were delivered at term unless complicated by obstetric or other medical factors.

Women were grouped according to White classification only for the purpose of statistical analysis.[4] For such analysis, White Class A was subdivided into A_1 (gestation diabetes, diet controlled) and A_2 (gestational diabetes, diet and insulin controlled). Class D (four) and Classes F and R (six) were grouped together to facilitate analysis. Statistical analysis was performed by the unpaired Student t test or χ^2 test where applicable.

Results

A total of 334 diabetic pregnancies were studied over the period 1979 to 1986 inclusive. When grouped according to White classification the distribution was Class A_1, 114; A_2, 103; B, 46; C, 61; D, F, and R, 10. The control population comprised 16,534 nondiabetic women delivered in the same obstetric unit over the same period of time. The incidence of preeclampsia in diabetic pregnancies was 9.9% (33/334) compared with 4.3% (716/16,534) in nondiabetic controls. The incidence of preeclampsia rose with increasing severity of diabetes according to White classification (Table I). After exclusion of diabetic patients with nephropathy or chronic hypertension the incidence was 8.9%.

The perinatal mortality rate for preeclamptic diabetic patients was 60 per 1000 live births (2/33) compared with 3.3 per 1000 live births (1/301) for normotensive diabetic patients. The perinatal mortality rate for all diabetic pregnancies was 9 per 1000 live births. Perinatal loss occurred at 25 and 27 weeks' gestation because of intrauterine death in two preeclamptic Class F diabetic patients after sudden exacerbation of hypertension and at 31 weeks' gestation because of prematurity after premature labor in a normotensive Class B diabetic patient.

There was no statistically significant difference in ma-

†Care of any kind (hospital or other) among women with cocaine-positive versus cocaine-negative results.

The use of cocaine by women is epidemic in many areas of the United States.[22] HIV and syphilis infections have been increasing in the same populations (poor, minority) in which cocaine has become a major drug of abuse.[4, 5, 23-27] Recent data on HIV incidence among army personnel, for example, found rates to be higher among black women than among white men.[23] Syphilis rates also have risen dramatically in many areas of the country. The incidence of primary and secondary syphilis among women in New York City rose from 541 cases in 1986 to 1841 by 1988. Congenital syphilis has shown a parallel rise, going from 60 to 357 cases in the same period.[28]

A higher prevelance of syphilis or HIV infection has significant implications for programs designed to address these problems in pregnancy. The Centers for Disease Control and the American College of Obstetricians and Gynecologists have promulgated guidelines for active intervention, within the context of prenatal care, for both illnesses.[29, 30] For HIV those programs focus on counseling, testing, and informed reproductive choice while for syphilis the focus is on routine testing and treatment. Cocaine has the potential to decrease the utility of these programs while increasing the need for them. In regard to pediatric HIV disease, for example, researchers have shown that "early identification of HIV infection . . . combined with appropriate counselling may decrease the number of children born with perinatal HIV infection, by allowing women to elect early termination of pregnancy."[31] Cocaine use, however, may nullify any potential public health benefits from prenatal counseling programs. The implications for pediatric HIV disease will become even more significant if, and when, antepartum therapy to reduce perinatal transmission becomes available.

We also found that many patients with positive rapid plasma reagin tests who did not have prenatal care had other contact with the health care system (emergency services). Cocaine use may increase the need to consider more aggressive surveillance and intervention for perinatal diseases in less traditional settings (e.g., syphilis screening in emergency rooms with community outreach to women who have positive tests, HIV counseling, and drug counselling on postpartum wards).

As noted, cocaine not only reduces the likelihood of treatment but also has been associated with increased acquisition of disease. The association of these diseases with drug use can partially be explained by the sharing of needles, which can act as vehicles of disease spread. Indeed 2 of 20 HIV-positive women in our study had past intravenous drug use documented in their records, and other HIV-positive patients also may have used intravenous drugs in the past but chose not to report it to health care personnel. Chaisson et al.[7] reported that the intravenous use of cocaine is associated with an increased risk of HIV infection among intravenous drug users. Although parenteral transmission of syphilis has not been as carefully documented as has been HIV transmission, spread from inadvertent inoculation has been reported.[32]

It has also been suggested that sexual risk taking contributes to the increased prevalence of HIV among women who use cocaine.[8, 9] Evidence for that phenomenon has come in large part from interviews with prostitutes, which suggest that exchange of sex for drugs

ternal age between preeclamptic and normotensive diabetic patients (preeclamptic diabetic patients, 27.9 years ± 5.6 SD; normotensive diabetic patients, 28.9 years ± 4.8 SD). The ratio of multigravid to primigravid patients was also similar in both groups (preeclamptic diabetic patients, 1:2.27 or 11/25; normotensive diabetic patients, 1:2.13 or 95/203). Delivery before 36 weeks' gestation was four times more likely when preeclampsia complicated a diabetic pregnancy (preeclamptic diabetic patients, 27.8%; normotensive diabetic patients, 7.8%). Mean birth weights were not significantly lower in preeclamptic diabetic patients compared with normotensive diabetic patients of the same gestational age when born after 35 weeks' gestation. Before 35 weeks' gestation birth weights were significantly lower in the preeclamptic patients with diabetes (Table II).

Mean fasting venous plasma glucose levels (preeclamptic diabetic patients, 88.2 mg/dl ± 21.6 SD; normotensive diabetic patients, 82.8 mg/dl ± 16.2 SD) and mean 1 hour postprandial venous plasma glucose levels (preeclamptic diabetic patients, 127.8 mg/dl ± 27.0 SD; normotensive diabetic patients, 126.0 mg/dl ± 23.4 SD) were not significantly different. Mean third trimester serum uric acid levels were significantly higher in preeclamptic diabetic patients (preeclamptic diabetic patients, 4.6 mg/dl ± 1.1. SD; normotensive diabetic patients, 4.1 mg/dl ± 0.9 SD; $p < 0.05$). Mean third trimester serum creatinine (preeclamptic diabetic patients, 0.67 mg/dl ± 0.13 SD; normotensive diabetic patients, 0.6 mg/dl ± 0.1 SD) and mean third trimester blood urea nitrogen levels (preeclamptic diabetic patients, 10.2 mg/dl ± 2.2 SD; normotensive diabetic patients, 9.1 mg/dl ± 2.2.) were not significantly different.

The incidence of chronic hypertension in all diabetic pregnancies was 3.89% (13/334) compared with 1.6% (265/16,534) in the nondiabetic population.

Table II. Comparison of mean birth weight of infants of preeclamptic diabetic and normotensive diabetic patients according to gestational age

Gestational age (wk)	*Mean weight (kg ± SD)*		*p Value*
	Preeclamptic diabetic infant	*Normotensive diabetic infant*	
38-41	3.46 ± 0.63	3.48 ± 0.51	NS
35-37	3.17 ± 0.65	3.29 ± 0.64	NS
32-34	1.61 ± 0.31	2.58 ± 0.49	<0.001

Comment

Diabetic pregnancies complicated by preeclampsia are of concern because of the increased perinatal morbidity and mortality seen in this situation.[1] Many of the early reports of diabetes in pregnancy commented on the high incidence of preeclampsia and the associated fetal loss.[2] Bachman[11] recorded a 21.7% incidence of preeclampsia in 1450 viable pregnancies reported by American and British clinics between 1947 and 1951. A later review by Kyle[2] of preeclampsia in diabetic pregnancies in 10 series from 1953 to 1960 suggested an average incidence of 25%.

With improved maternal-fetal management and surveillance there has been a suggestion that the incidence of preeclampsia in diabetic pregnancies is declining.[12] Kitzmiller[12] noted an incidence of only 5% preeclampsia in 147 type I diabetic patients, and suggested that modified bed rest at home was in part responsible for the decline.[12] However, Kitzmiller excluded Class F diabetic patients from the analysis on the basis that a diagnosis of superimposed preeclampsia in women with diabetic nephropathy was impossible to make with certainty. A review of pregnancy complications among diabetic women (1965 to 1985) found an overall rate of 11.7% in four studies.[5] Two of these studies failed to find an increased incidence of preeclampsia in diabetic pregnancies (Classes A-R,[12] and Class A alone[13]). Two other studies suggested a significantly higher rate of preeclampsia in diabetic patients (Classes B-R[14] and Classes A-R[16]). The present study is the first prospective study of which we are aware that compares preeclampsia in diabetic pregnancies with a nondiabetic group. It confirms the finding of some retrospective studies of diabetic pregnancies that the incidence of preeclampsia increases with the severity of diabetes by White classification.

The reasons suggested for this increased incidence have been numerous. Hagbard[15] concluded that the increased rate of preeclampsia seen in his series was because diabetic patients were more likely to be primigravid women. Our study has failed to confirm this suggestion inasmuch as a similar ratio of primigravid/multigravid women were seen in both preeclamptic and normotensive diabetic pregnancies. Kitzmiller et al.[12] postulated that the high incidence of preeclampsia was related to inclusion of Class F diabetic patients in those studies. The diagnosis of superimposed preeclampsia in Class F diabetic patients is impossible to make with certainty because many diabetic patients with nephropathy are hypertensive and show worsening of proteinuria as the pregnancy progresses. However, our study shows an overall incidence of 8.9% of preeclampsia when Class F diabetic patients and those with chronic hypertension are not included. This is still double the nondiabetic incidence (4.3%), and suggests that other factors must be implicated. Results of renal function testing in the form of third trimester blood urea nitrogen and serum creatinine levels were also similar in both preeclamptic and normotensive pa-

might be linked to outbreak of sexually transmitted diseases.[8, 9] These interview-based studies may be subject to recall bias since the stigma attached to intravenous drug use may be greater than that associated with nonparenteral use. Our findings are consistent with a hypothesis of sexual transmission. None of the HIV-positive patients had opiates in the urine and eight of 10 denied intravenous drug use. Overall, athough misclassification bias must be strongly suspected, only 7.8% of patients who acknowledged cocaine indicated that they injected it.

The mechanisms through which cocaine enhances sexual risk taking still remain to be clarified. Some risk behaviors may have financial incentive. Although an individual "dose" of cocaine ("crack") may be cheap, the effect of the drug is short-lived and multiple dosing occurs throughout the day. The mechanisms available to indigent women to support a cocaine habit are severely limited and a direct barter of sexual favors for cocaine is not an unlikely event.[33] Cocaine also may have physiologic effects relating to sex; it has been reported both to enhance and to inhibit sexual activities.[34]

A potential for several types of bias exists in this study. Misclassification bias exists in this study since cocaine users who have not recently been exposed to cocaine will be classified as nonusers. This bias, however, would work in the direction of the null hypothesis and in fact understate the influence of the drug on disease acquisition. Cocaine users may be less likely than nonusers to seek treatment for syphilis, and therefore cocaine users may be more likely to be untreated and identified in a cross-sectional study such as this one. This bias would tend to overstate the association. These biases would not affect the association of HIV and cocaine use since evidence of infection is not influenced by treatment. Finally cross-sectional studies limit the inferences that can be made regarding the temporal sequence of cause and effect. Prospective designs will be necessary to overcome these limitations.

In sum, the epidemic of HIV infection and syphilis among pregnant women in this community has been confirmed and an association with cocaine has been found. Cocaine also has been linked to reduced utilization of prenatal care services by infected individuals. The importance of HIV infections, syphilis infections, and cocaine use to the reproductive health of minority women in these communities makes it vital that these associations be verified and the contribution of risk sexual behaviors be clarified. In the interim prevention efforts should begin to focus on the treatment of cocaine use since it may be contributing substantively to the spread of syphilis and HIV and to the failure of patients to receive counseling and treatment. Innovative efforts also are needed to reach "unregistered" pregnant women with HIV counseling and syphilis treatment programs.

tients with diabetes, suggesting that underlying renal disease may not be the factor. However, more sophisticated testing for early diabetic renal involvement through microalbuminuria testing may be required to confirm this finding.

The diabetic control in both preeclamptic and normotensive diabetic groups was similar, as is evident from comparable mean plasma glucose levels before meals and 1-hour after meals during the third trimester. Thus ensuring euglycemia in diabetic pregnancies does not appear to afford protection from preeclampsia.

Earlier surveys of preeclampsia in diabetic pregnancies had suggested that an important factor might be that persons with diabetes were likely to be older because medical advice tended to delay or advise against pregnancy.[2] Our study fails to support this theory inasmuch as maternal age at delivery is the same in preeclamptic and normotensive diabetic pregnancies.

The complication of a diabetic pregnancy by preeclampsia greatly increases fetal morbidity and mortality, as reflected in this series by a significant increase in pernatal mortality (60:1000 preeclamptic diabetic patients compared with 3.3:1000 normotensive diabetic patients) and a significant decrease in birth weight before 36 weeks' gestation. Until the cause of preeclampsia is further elucidated, the nature of this deleterious effect on diabetic pregnancies remains hypothetical. Preeclampsia is characterized by changes in the production rates of several arachidonic acid metabolites.[17] The vasodilating and platelet-aggregation inhibiting prostaglandins (PGI_2 and PGE) are increased in normal pregnancy, but in contrast a relative increase in vasoconstricting, platelet-aggregating prostaglandins (thromboxane A_2 and PGF_2) is seen in preeclampsia. Thus a change in the balance between these two groups of prostaglandins may play an important role in the pathogenesis of preeclampsia. Similar alterations in the metabolism of arachidonic acid to PGI_2 and thromboxane A_2 are seen in diabetes mellitus.[18] Vascular prostacyclin (PGI_2) synthesis is decreased in both patients and experimental animals with diabetes mellitus, and platelet synthesis of thromboxane A_2 is increased. Prostacyclin synthesis is severely depressed in the umbilical arteries of neonates of mothers with both gestational diabetes and type I diabetes mellitus.[19] The increased ratio of thromboxane A_2 to prostacyclin favors increased platelet aggregation and vasoconstriction, which could play a role in predisposition toward preeclampsia in the pregnant patient with diabetes. The altered thromboxane/prostacyclin ratio can be reversed in both diabetic subjects and in preeclampsia by low-dose aspirin therapy.[20] This suggests the possibility of future prophylactic therapy by cyclooxygenase inhibitors for prevention of preeclampsia in the pregnant diabetic patient.

Rupture of unscarred uterus in primigravid woman in association with cocaine abuse

Whitney Gonsoulin, MD, David Borge, MD, and Kenneth J. Moise, Jr., MD
Houston, Texas

Cocaine use in pregnancy has been associated with preterm labor and abruptio placentae. We report a case of rupture of an unscarred uterus necessitating hysterectomy in a patient after cocaine abuse. (Am J Obstet Gynecol 1990;163:526-7.)

Key words: Ruptured uterus, cocaine abuse

As the increase of cocaine abuse in the United States has occurred, so has the use of cocaine in the pregnant population. The association of cocaine abuse with preterm labor, abruptio placentae, and placenta previa has been previously described.[1] We report a case of a primigravid woman with rupture of an unscarred uterus, who presented with abdominal pain after recent cocaine abuse.

Case report

A 19-year-old, nulliparous, black woman was first seen at 32 weeks' gestation complaining of a 2-day history of progressive, unremitting abdominal pain. She denied vaginal bleeding, rupture of membranes, or change in fetal activity. Her pregnancy was complicated by lack of prenatal care and daily intravenous cocaine use. Her last admitted use of cocaine was 2 days before admission, which coincided with the onset of abdominal pain.

Medical history was unremarkable for previous pregnancies or uterine instrumentation. Vital signs were stable. The physical examination was remarkable for extensive needle tracks and edema of the upper extremities. Abdominal examination revealed a fundal height of 30 cm; the uterus was firm and tender to palpation. Vaginal examination revealed no evidence of bleeding or ruptured membranes and the cervix was closed and soft.

The fetal heart tracing was reactive without decelerations and with a rate of 140 to 150 beats/min. The laboratory findings were hematocrit 31%, coagulation profile normal, and urine negative for protein. Sonographic examination was remarkable for a complete placenta previa, possible abruptio placentae, and decreased amniotic fluid. Estimated fetal weight was 1417 gm (<10th percentile for 32 weeks' gestation), suggesting intrauterine growth retardation.

An urgent exploratory laparotomy was performed for management of an acute abdomen with possible abruptio placentae. On opening the abdomen, the fetus was noted in the right upper quadrant of the peritoneal cavity and the uterus was ruptured. A viable female fetus weighing 1510 gm was delivered with Apgar scores of 5 and 7 at 1 and 5 minutes, respectively. Umbilical cord gas values were as follows: arterial pH 7.25, P_{O_2} 41 mm Hg, and P_{CO_2} 52 mm Hg; venous pH 7.27, P_{O_2} 42 mm Hg, and P_{CO_2} 49 mm Hg.

The uterine rupture was anterior and longitudinal; it extended from the fundus to the lower segment.

Evaluation of the placental site revealed the presence of a retroplacental clot and an adherent placenta. Because of the irreparable damage to the uterus, a hysterectomy, a bilateral salpingectomy, and a right oophorectomy were performed. The patient required one unit of packed red blood cells intraoperatively. Urine toxicology screen was positive for cocaine. The patient's postoperative course was unremarkable. Results of the infant's examination at birth were consistent with intrauterine growth retardation.

Placenta percreta and abruptio placentae were confirmed on pathologic evaluation, as were left hydrosalpinx and chronic right salpingitis.

Comment

Rupture of the unscarred uterus has been associated with grand multiparity, cephalopelvic disproportion, and oxytocin and has rarely been reported in the primigravid woman.[2] Other causes include previous uterine surgery, uterine abnormalities, cornual pregnancy, hydatidiform mole or chorioadenoma destruens, abruptio placentae, and placenta percreta.[2] In this case the contributing factors were placenta percreta and abruptio placentae. The association of cocaine abuse with rupture of the uterus has not, to our knowledge, been reported previously.

Abdominal pain, uterine tenderness, loss of fetal heart tones, hemorrhage, and shock are the most common symptoms of uterine rupture. Abruptio placentae also may present with these symptoms and ultrasound may help differentiate these two conditions. Patients presenting with the above symptoms should be questioned for drug use, and drug screening may be beneficial in those populations known to be at risk. Prompt abdominal exploration may be necessary and was associated with the survival of the infant in our case. Hysterectomy was required in this patient, but suture of the uterus with a less extensive defect may be possible. Cocaine is thought to cause placental vasoconstriction, decreasing blood flow to the fetus. In addition, increased norepinephrine levels may cause an increase in uterine contractility.[1] The hypertension and vasoconstriction associated with cocaine use might have been responsible for the abruptio placentae. A weakened uterine wall from placental percreta may have predisposed our patient to uterine rupture when tetanic contractions occurred as a secondary result of cocaine use. Obstetricians must be aware of these additional potential complications from cocaine abuse in their patients.

Prognosis for twins with birth weight <1500 gm: The impact of cesarean section in relation to fetal presentation

Håkan Rydhström, MD
Lund, Sweden

The purpose of this study of twins weighing <1500 gm was to evaluate the impact of cesarean section on intrapartum and neonatal mortality, as well as on cerebral palsy and mental retardation. National data held at the Medical Birth Registry was used for identification of cases. The original medical records were retrieved for 862 such twins born between 1973 and 1983. Twins with cerebral palsy and/or mental retardation born between 1973 and 1980 were identified by questionnaires to all rehabilitation centers for disabled children, offices for the Provision of Care for the Mentally Retarded, and to all local Boards of Education throughout Sweden. The analyses, including calculation of relative risk and 95% confidence interval, were performed after stratification for birth weight (250 gm classes) and period of delivery (1973 to 1976, 1977 to 1980, 1981 to 1983). The cesarean section rate increased from 7.7% (1973 to 1976), and 40.5% (1977 to 1980) to 68.9% (1981 to 1983). Concomitantly, intrapartum and neonatal mortality decreased markedly (51.7% to 29.1%) particularly for twin II but to a much lesser extent for twin I. The relative risk for intrapartum and neonatal mortality (vaginal/abdominal birth) did not increase significantly for twin I in vertex presentation (relative risk 2.0, 95% confidence limits 0.9 to 4.3), for twin I in breech presentation (relative risk 1.8, 95% confidence limits 0.7 to 4.3), for twin II in vertex presentation (relative risk 0.6, 95% confidence limits 0.2 to 1.6), or for twin II in breech presentation (relative risk 1.5, 95% confidence limits 0.7 to 3.0). The rate of cerebral palsy and/or mental retardation was 8.8% during 1973 to 1976 and 8.0 during 1977 to 1980 ($\chi^2 = 0.1$, $p > 0.05$). For twins born in breech presentation the handicap rate in the first period (cesarean section rate 6.0%) was the same as in the second period (cesarean section rate 59.6%). The analysis failed to reveal any significant impact of abdominal birth on the fetal outcome for low-birth-weight twins, even when fetal presentation was taken into consideration.
(Am J Obstet Gynecol 1990;163:528-33.)

Key words: Cerebral palsy, cesarean section, neonatal mortality, mental retardation, twins

During labor low-birth-weight twins have an increased risk for malpresentation, cord accidents, and placental separation.[1,2] To avoid these hazards, abdominal delivery has been proposed for pregnancies involving twins with an estimated birth weight <1500 gm.[3] Others have suggested that an attempted vaginal delivery is appropriate for twins in vertex-vertex presentation[4,5]; thus women with the first or the second twin in breech presentation are to be delivered abdominally.

However, most studies have been based on small numbers of cases and these have not been geographically defined populations, which makes interpretation of the results difficult.[6,7] Therefore recommendations for mode of delivery, particularly for twins in breech presentation, have been based on results from studies on singletons.[1,2]

The purpose of this study was to evaluate the impact of cesarean section on intrapartum and neonatal mortality and on long-term morbidity in a relatively large population. Data from nearly all twins weighing <1500 gm, born in Sweden during an 11-year period were used.

Material and methods

Between 1973 and 1983, 539 twin pairs with at least one twin weighing <1500 gm at birth were identified in a scrutiny of national data at the Medical Birth Registry, Stockholm. Two hundred sixteen of the cotwins weighed ≥1500 gm; these were not included in the analysis; thus 862 twins for the final analysis. Included in the Medical Birth Registry are twin pregnancies reaching ≥28 weeks or <28 weeks if at least one twin was alive at birth. Compared with the official statistics[8] 2.4% of all women with a twin pregnancy delivered in Sweden during the study period were missing from the Medical Birth Registry.

Twenty-eight twins with lethal malformations and 53 pregnancies with antenatal fetal death were excluded from the analyses. To evaluate the effects of factors other than mode of delivery on intrapartum and neonatal mortality (twins who died during or up to 28 days

after delivery) the original medical records of all twins were retrieved. The presentation of the fetus was not recorded in 25 cases (3.0%) in the collected material.

In 4.6% (40 twins in 25 pregnancies from 23 different hospitals) the medical records were not found. The missing twins had a similar birth weight distribution compared with the collected material. Intrapartum and neonatal mortality was 47.5% (19/40), not significantly different from that in the study population ($\chi^2 = 0.3$, $p > 0.05$).

Each newborn in Sweden is given a unique personal identification number. Given the identification number, the Central Bureau of Statistics offers access to a population-based registry with up-to-date information (not older than 14 days) on domicile. This made it possible to identify twins with cerebral palsy and/or mental retardation ≥8 years after birth. A total of 357 twins born between 1973 and 1980 were followed up to school age. A questionnaire was sent to the rehabilitation centers ($n = 30$) for disabled children, as well as to the offices for Provision and Care for the Mentally Retarded ($n = 24$) throughout Sweden. A similar questionnaire was distributed to each local Board of Education ($n = 284$) asking for information on school attendance. As a rule, any child with an IQ score below 70 is placed in a special school. All rehabilitation centers, and all local Boards of Education responded to the questionnaire, whereas three of 24 offices for the mentally retarded did not. Twins with Down syndrome were excluded from the analysis.

The Mantel-Haenszel method was used in the statistical analysis.[9] Stratification was made for period of birth (1973 to 1976, 1977 to 1980, 1981 to 1983) and for birth weight (500 to 749 gm, 750 to 999 gm, 1000 to 1249 gm, and 1250 to 1499 gm). The relative risk for intrapartum and neonatal mortality (vaginal/abdominal birth) was calculated with 95% confidence limits.[10] The χ^2 test with 1 degree of freedom was used to analyze differences between groups. A p value <0.05 was considered significant.

Results

The cesarean section rate increased from 7.7% in the first study period (1973 to 1976) to 68.9% in the last period (1981 to 1983), whereas intrapartum and neonatal mortality decreased from 51.7% to 29.1% (Table I). Intrapartum and neonatal mortality for twin II decreased from the first to the last study period, and in a similar manner for twins born delivered vaginally and abdominally, whereas intrapartum and neonatal mortality for twin I remained virtually constant. Twin II had a significantly higher overall intrapartum and neonatal mortality than twin I (47.0% versus 38.6%; $\chi^2 = 6.2$, $p < 0.05$), although this difference was balanced in the last study period.

In the total material the relative risk for intrapartum and neonatal mortality (vaginal/abdominal birth) was 1.5 and the 95% confidence limits 1.0 to 2.3 (Table II). No significant difference was found in intrapartum and neonatal mortality for twin I or twin II in vertex or breech presentation. For twin I in breech presentation an insufficient number of twins rendered statistical testing invalid; the analysis was therefore performed without stratification for period of delivery.

A separate analysis was made for twins born vaginally compared with those delivered by cesarean section when the only indication for the operation was prematurity. In this way the influence of mode of delivery on intrapartum and neonatal mortality could be studied in the most detailed possible way. No significant differences in intrapartum and neonatal mortality in the vaginal and cesarean delivery groups could be found (Table III).

The autopsy rate for dead twins was 83%. The primary cause of neonatal death was immaturity. Other causes were infection and difficult or traumatic delivery.

Statistical analysis after stratification for birth weight (250 gm classes) and period of delivery (three classes). Relative risk (vaginal/abdominal birth) with 95% confidence interval.

The rate of twins with cerebral palsy, mental retardation, or both at follow-up 8 years or more after birth is shown in Table IV. One twin died after the neonatal period but before follow-up, leaving 357 infants in the final analysis group. The handicap rate did not change from the first to the second period (8.8% versus 8.0%, respectively). A similar rate was found for handicapped twins ($\chi^2 = 0.5$; $p > 0.05$) born in breech presentation during the first period (cesarean section rate 6.0%) and in the second period (cesarean section rate 59.6%). The handicap rates were similar for twin I (9.4%) and twin II (7.2%).

The cumulative birth weight distributions were similar for vaginal and abdominal births (Fig. 1); however, twins born vaginally in the lowest stratum (500 to 749 gm) weighed 50 gm less. In 85% of twin pregnancies delivered by cesarean section, twins were detected more than 1 day before delivery (Fig. 2). For vaginal births the corresponding figure was <50%. Detection of twin II after birth of twin I occurred in about 10% and 40%, respectively, for abdominal versus vaginal birth.

Comment

The Medical Birth Registry has collected antenatal, intrapartum, and neontal data on nearly all births in Sweden since 1973. Use of this population-based data base afforded the opportunity to collect information on a relatively large number of twins with birth weights <1500 gm. Because presentation is not recorded in the data base, the original medical records were retrieved, which further improved the quality of the data. The deliveries in this study occurred during a period just before the introduction of routine ultrasonographic scanning for all pregnant women (for confirmation of gestational age) in Sweden. This explains the use of birth weight rather than gestational age as an index of maturity.

For twin I in vertex presentation, no significant difference in intrapartum and neonatal mortality was found between vaginal and abdominal birth after stratification for birth weight. Further evidence that abdominal birth did not improve the prognosis to any extent is that intrapartum and neonatal mortality for

*Including twins without known presentation.

twin I remained virtually constant for vaginal births, as well as for abdominal births during the first two study periods (Table I).

For twin I in breech presentation, stratification for period of delivery was not done because of an insufficient number of cases. Thus vaginal birth during the first period (when the overall intrapartum and neonatal mortality was higher) was compared with abdominal birth during the last period (when the overall intrapartum and neonatal mortality was lower). This limitation in the analysis would tend to increase the relative risk for vaginal birth. However, the relative risk for intrapartum and neonatal mortality remained insignificant, suggesting that cesarean birth is not a significant factor influencing changes in intrapartum and neonatal mortality.

Intrapartum and neonatal mortality for twin II decreased consistently during the study period but the analysis failed to show that twin II born abdominally had a significantly lower intrapartum and neonatal mortality than twins born vaginally. This is in contrast to the results of other studies.[3, 11] For twin II in vertex presentation the relative risk for intrapartum and neonatal mortality was below 1.0.

When the results are evaluated, several possible confounding factors must be considered. In Sweden a pediatrician is always present at a cesarean birth. This was probably not usually the case at vaginal twin births during the study period. It should be noted that the present analysis might include twins born when the obstetrician may have underestimated viability and may have refrained from intervening because of fetal indications, accordingly influencing the results of vaginally born twins negatively. Support for this negative influence comes from the birth weight analysis of the birth weight in the lowest stratum (500 to 749 gm) in which the twins born vaginally weighed 50 gm less than those born abdominally. Admittedly, only 56 twins had a birth weight <750 gm.

The interpretation of the results is complicated by the fact that when cesarean section is performed because of life-threatening conditions for the fetus (e.g., abruptio placentae) the cesarean section would appear to be a risk factor. The estimated relative risk could contain two counteractive components: one a confounding effect of life-threatening conditions, the other a beneficial effect of cesarean section on fetal mortality. To reduce the former effect, a separate analysis was made in which the sole indication for cesarean section was prematurity. Because of the paucity of cases, this analysis was restricted to twin I or twin II (irrespective of presentation) or to vertex or breech presentation (irrespective of order of birth). In none of the four groups tested was intrapartum and neonatal mortality significantly lower for twins born abdominally than for vaginally born twins.

Most previous studies have indicated the importance of an early twin diagnosis to improve prognosis.[5, 7] A remarkable finding was that about half of the twin pregnancies with vaginal delivery were detected less than 1 day before the delivery, whereas the corresponding figure for abdominal births was 10%. This indicates that women with twin pregnancies finally to be delivered abdominally might have benefited during the pregnancy, compared with women who gave birth normally.

The autopsy rate in this study was 83%. I refrained from further analysis of cause of death for several reasons. It is probable that the results of an autopsy performed in 1973 (when few pediatric pathologists were available) are not strictly comparable with one per-

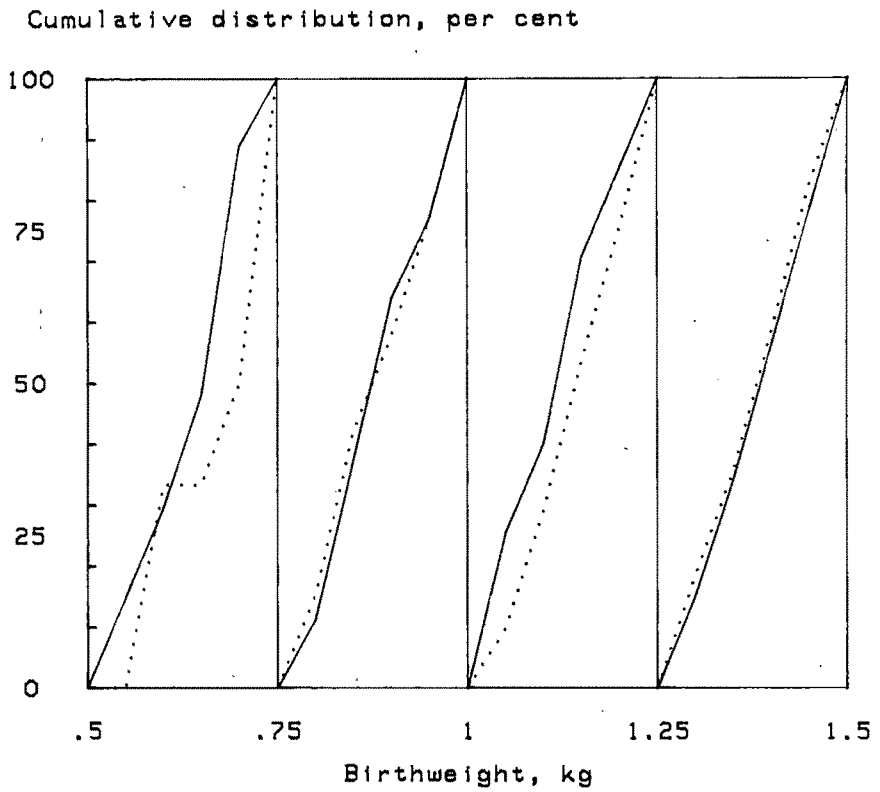

Fig. 1. Cumulative birth weight distribution for twins with vaginal birth *(solid line)* and abdominal birth *(dotted line)*.

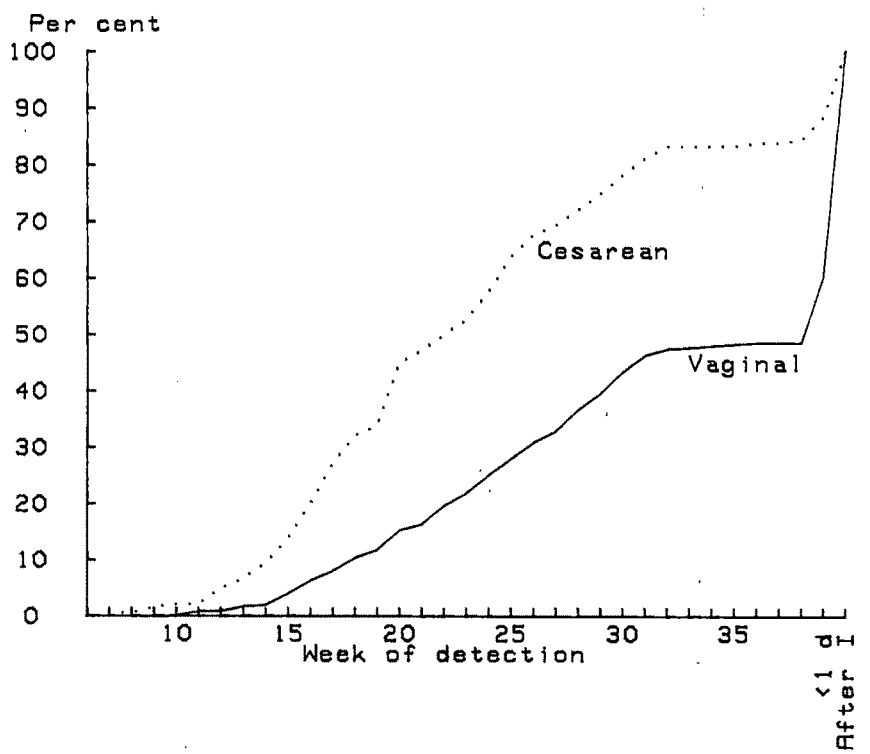

Fig. 2. Week of detection; *<1 d* signifies detection less than 1 day before delivery. A considerable number of twins were not detected until after birth of twin I *(after I)*.

formed in 1983. More significantly, classification by clinical cause is inadequate because several of the definitions are highly subjective.[12] The major impact of the high autopsy rate was that twins with lethal malformations could be excluded from the analysis.

A significant feature of studies of handicapped infants in the Scandinavian countries is the possibility to locate each single infant in a birth cohort, irrespective of the interval between delivery and follow-up. This is made possible by (1) the unique personal identification number given to each newborn (and present in Medical Birth Registry) and (2) information on domicile available from the Central Bureau of Statistics. With information on domicile for each single twin, it is possible to gain reliable data on, for example, school attendance (with one exception, for infants living abroad).

It is noteworthy that in this study 8% to 9% of all twins weighing <1500 gm had cerebral palsy and/or mental retardation at follow-up, 8 years or more after delivery. This proportion did not decrease significantly from the first to the second period (8.8% versus 8.0%). The latter figure (8.0%) could conceivably have been higher because infants with mental retardation are sometimes not identified until or after the beginning of obligatory schooling at 7 years of age.[13] Obviously the rising cesarean section rate seems to have influenced the morbidity rate to a very limited extent. This conclusion includes twins in breech presentation in which the cesarean section rate increased about tenfold from the first to the second period.

A marked overall reduction of the intrapartum and neonatal mortality was seen during the study period, although to a much lesser extent for twin I than for twin II. Concomitantly the cesarean section rate increased from 7.7% to 68.9%. To what degree this increase in abdominal deliveries has contributed to the improved mortality figures cannot be separated from other factors influencing the results. Nevertheless, the cesarean section rate seemed to have little impact on intrapartum and neonatal mortality or cerebral palsy and mental retardation related to twin presentation.

Recurrent acute fatty liver of pregnancy

John R. Barton, MD,[a] Baha M. Sibai, MD,[a] William C. Mabie, MD,[a] and Douglas R. Shanklin, MD[a, b]

Memphis, Tennessee

The first reported case of recurrent acute fatty liver of pregnancy confirmed by biopsy is described. In this case a high index of suspicion led to an early diagnosis and intervention with resultant improved maternal and fetal outcome. Electron microscopic examination of a liver biopsy specimen proved more beneficial in confirmation of the diagnosis compared with routine microscopic examination. (AM J OBSTET GYNECOL 1990;163:534-8.)

Key words: Acute fatty liver, electron microscopy, pregnancy

Acute fatty liver of pregnancy is a rare but potentially fatal complication of the third trimester of pregnancy. The exact cause of acute fatty liver of pregnancy is still debatable; however, it has not been described to recur in subsequent pregnancies.[1, 2] We previously reported use of computed tomography in diagnosis of acute fatty liver of pregnancy.[3] The patient described in that report has since returned with a subsequent pregnancy also complicated by acute fatty liver of pregnancy. This article describes the recurrence.

Case report

A 37-year-old black woman, gravida 5, para 3, abortus 1, was seen at 30.5 weeks' gestation with a 2-day history of nausea, vomiting, anorexia, and a low-grade fever. The patient further noted a 1-day history of epigastric pain and decreased fetal movement. Subjectively, the patient offered that the symptoms she was experiencing were identical to those of her previous pregnancy complicated by acute fatty liver of pregnancy and intrauterine fetal demise. Physical examination revealed a blood pressure of 110/80 mm Hg and a pulse of 84 beats/min with no significant orthostatic changes. Temperature was 37.8° C. The abdomen was nontender with fundal height of 22 cm. A single fetus in vertex presentation was noted with a fetal heart rate of 136 beats/min. The cervix was 1 cm dilated but uneffaced. Slight scleral icterus was present, but there was no edema of the extremities. Liver function tests and coagulation profiles had returned to normal 3 weeks post partum after her previous episode of acute fatty liver of pregnancy 16 months earlier. Initial laboratory data included a serum aspartate aminotranferase serum of 790 U/L, serum alanine aminotransferase of 865 U/L, total bilirubin 3.3 mg/dl, γ-glutamyl transpeptidase 342 U/L (normal 5 to 55 U/L), alkaline phosphatase 362 U/L, uric acid 11.4 mg/dl, serum ammonia 28 μmol/L (normal 11 to 35 μmol/L), lactic dehydrogenase 402 U/L, platelet count 307,000/mm³, and plasma glucose 62 mg/dl. The bleeding time was 4 minutes, prothrombin time 13.0 seconds, partial thromboplastin time 33.6 seconds, and hematocrit 39%. A urine dipstick test for protein was negative. A nonstress test was nonreactive with decreased variability and a baseline fetal heart rate of 180 beats/min. The biophysical profile score was 2/10 (2 only for fluid, which was subjectively decreased). The patient had a primary classic cesarean section while under general anesthesia. A 990 gm viable female with Apgar scores of 2 and 5 at 1 and 5 minutes, respectively, was delivered. An arterial cord blood gas sample revealed pH 7.28, P_{CO_2} 51 mm Hg, P_{O_2} 21 mm Hg, with a base excess of −2.8 mmol/L. A Tru-Cut (Travenol Laboratories, Inc., Deerfield, Ill.) needle biopsy of the liver was performed under direct visualization through the same abdominal incision. The patient was transferred to the obstetric intensive care unit for recovery and was monitored there for 3 days. Computerized tomography of the liver was performed on postoperative day 1 and revealed subtle areas of decreased density predominantly in the right lobe of the liver in comparison with the splenic density. These areas of decreased density were consistent with focal fatty infiltration. The patient required intravenous hydralazine on two occasions during postoperative day 1, but none thereafter. Serial laboratory evaluations of plasma glucose remained normal throughout the hospitalization. Elevated aminotransferase and lactic dehydrogenase levels normalized within 7 days of delivery. All hepatitis B titers were negative. Hepatitis A IgG antibody remained positive as detected in the previous pregnancy. The patient was discharged on postoperative day 8. Respiratory insufficiency of prematurity and patent ductus arteriosus developed in the infant, who remained in the neonatal

intensive care unit for 53 days but was discharged at that time in good condition.

Microscopic examination of the liver biopsy was compared with the biopsy from our patient's earlier pregnancy. The current biopsy revealed diffuse low-grade panlobular microvesicular fatty change (steatosis) (Fig. 1) with low-grade portal and parenchymal chronic inflammation, histopathology similar to that previously reported.[3] This fatty change was obvious on hematoxylin and eosin stain; thus oil red O or other special stains were not considered necessary. These lesions were fully consistent with acute fatty liver of pregnancy,[4] but fell short of the histologic changes of severe, often fatal, acute fatty liver of pregnancy.[5, 6] These changes are effectively pathognomonic for acute fatty liver of pregnancy at the light microscopic level.[1-6]

Electron micrographs revealed cellular changes considered to be diagnostic of acute fatty liver of pregnancy. There was maintenance of overall lobular architecture. The vacuolar appearance on hematoxylin and eosin staining was matched by microvesicular fatty deposits with distinctive membrane barriers. There was abundant β-glycogen often bordering the fatty vesicles. Most mitochondria were intact, reflecting the condensed state. The mitochondria in Reye's syndrome have been described as flocculent[7, 8] or with diminished matrix granules,[9] neither of which were detected here. Similarly, lipophagosomes are found frequently in hepatocytes in Reye's syndrome.[7, 8, 10] Only tiny residual bodies were found in the hepatocytes in our patient (Fig. 2). However, rare intramitochondrial crystalline inclusions were noted (Fig. 3), but this has been seen in acute fatty liver of pregnancy[11] as well as in cases of hepatitis B.[12, 13] The nuclei were normal with dispersed grains of glycogen.

Comment

This patient demonstrates that recurrent acute fatty liver of pregnancy can recur. The lack of previous reports of recurrent acute fatty liver of pregnancy may be related to medical counseling against further pregnancies, infrequent use of liver biopsy in such cases, independent patient decisions against further pregnancies, or a low incidence of recurrence.

The case further illustrates that early diagnosis and intervention can result in excellent maternal and fetal outcome in acute fatty liver of pregnancy. The patient was delivered within 60 hours of her initial symptoms and within 3 hours after admission to the hospital. The management of acute fatty liver of pregnancy remains immediate delivery and supportive care.

Although routine microscopic examination was not strictly pathognomonic for acute fatty liver of pregnancy, it was fully consistent. The ultrastructure confirmed the diagnosis. The extent of histologic findings

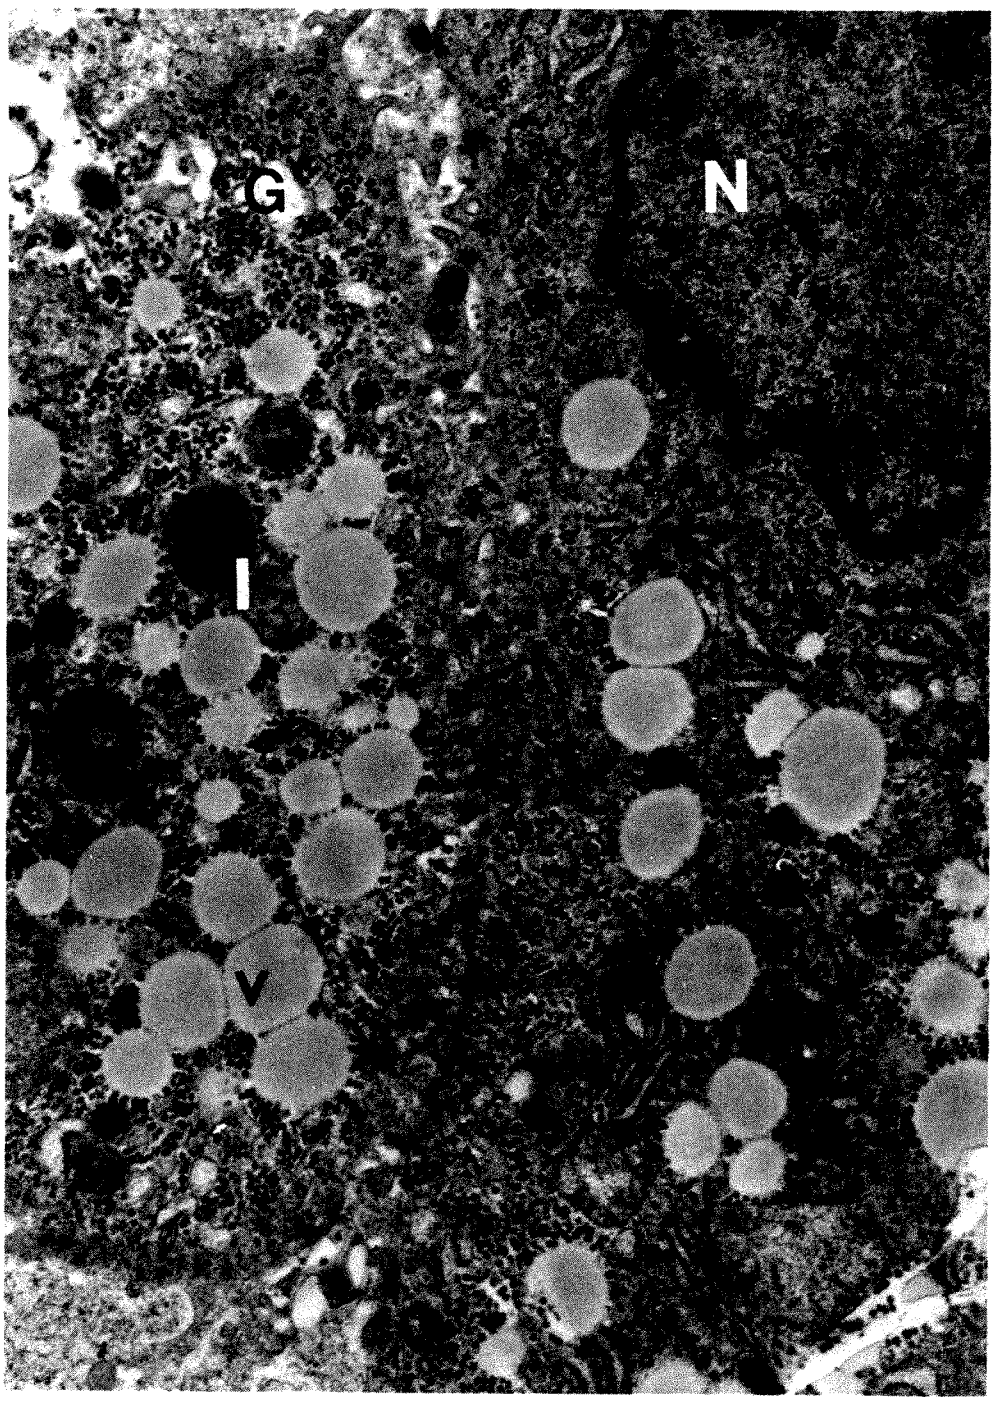

Fig. 2. Transmission electron micrograph of liver biopsy specimen. Microvesicular fatty change *(V)*, abundant β-glycogen *(G)*, and intact, condensed mitochondria *(M)*. Rare mitochondrion with crystalline inclusions *(I)*. Hepatocytic nuclei *(N)* also contain some β-aggregates of glycogen. (Original magnification ×8000.)

can be attributed to early diagnosis and treatment. We suggest routine biopsy for electron microscopy as a means to establish the diagnosis definitively.

Microvesicular cytoplasmic fatty droplets in hepatocytes are also observed in Reye's syndrome.[7-10, 14] Reye's syndrome was unlikely in this patient because of her age, denial of recent aspirin use, no recent clinically apparent viral illnesses, and a total bilirubin consistently >3 mg/dl. Moreover, the ultrastructural distinctions between Reye's syndrome[7-10, 14] and acute fatty liver of

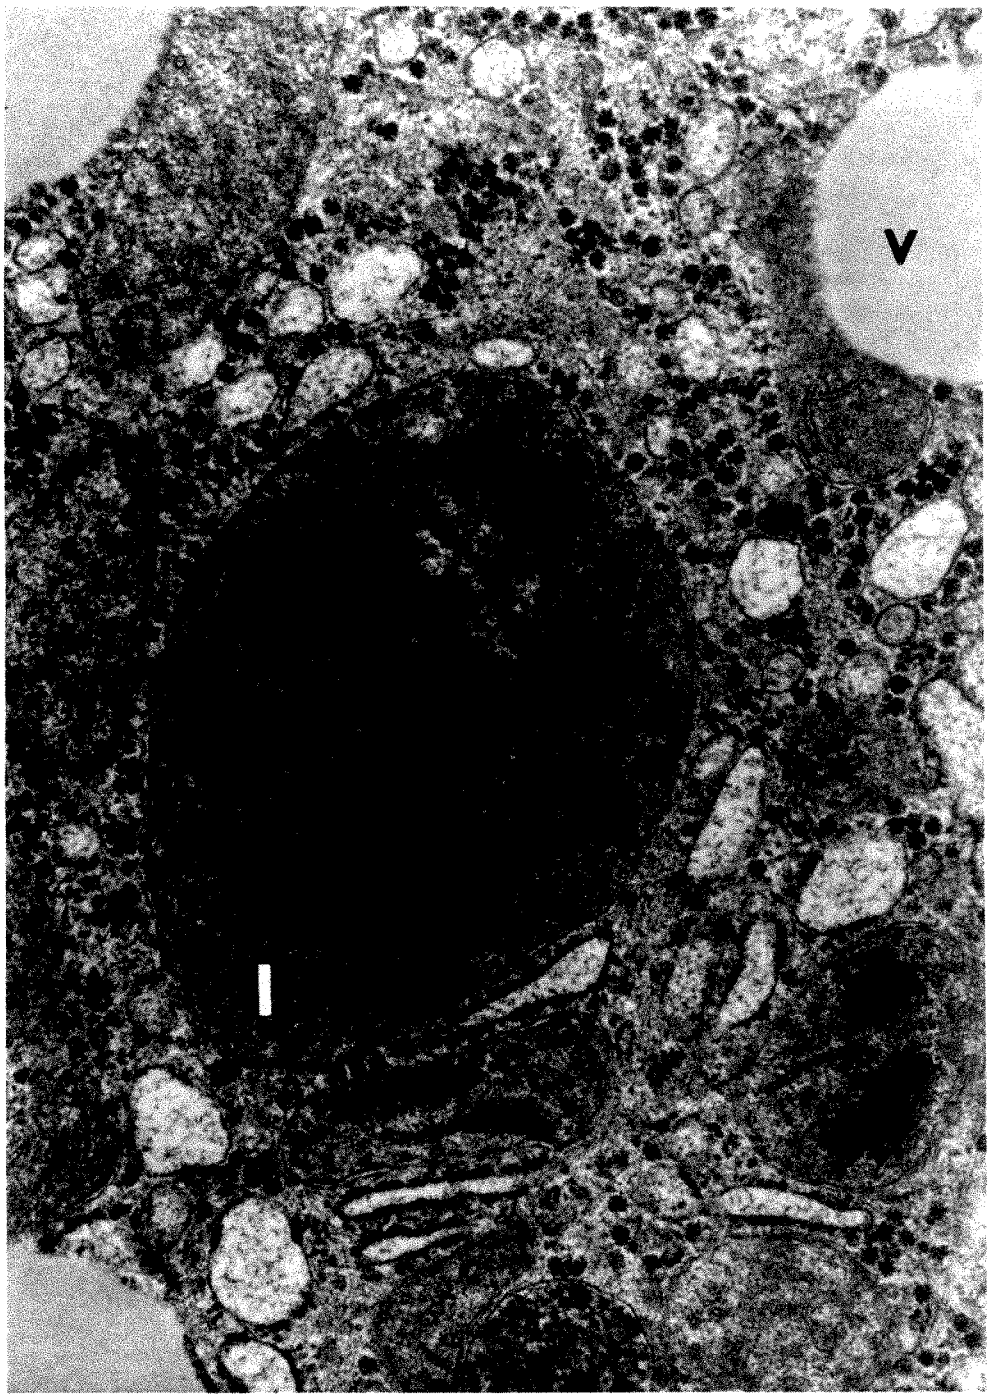

Fig. 3. Transmission electron micrograph of liver biopsy specimen. Microvesicular fatty change *(V)* and enlarged mitochondrion containing numerous crystalline inclusions *(I)*. (Original magnification ×58,700.)

pregnancy[11] indicated that our patient is an example of recurrent acute fatty liver of pregnancy.

Subsequent pregnancies in patients with previous acute fatty liver of pregnancy should be monitored closely for signs and symptoms of acute fatty liver of pregnancy, especially in the third trimester. With a high index of suspicion, an earlier diagnosis of recurrent acute fatty liver of pregnancy can be made, resulting in more rapid intervention and improved maternal and fetal outcome.

We thank Patrick J. Dean, MD, for providing the slides from the liver biopsy from the first pregnancy for additional review. We thank Deborah Hollis and Frank Moretta for the electron micrographs used in study of the case.

Postpartum coronary artery dissection followed by heart transplantation

Piero Curiel, MD,[a] Giansenio Spinelli, MD,[a] Antonio Petrella, MD,[b] Alessandro Gori, MD,[b] Renata De Maria, MD,[c] Edgardo Bonacina, MD,[d] and Edoardo Gronda, MD[e]

Prato and Milan, Italy

A rare case of coronary artery dissection was observed in a 33-year-old woman on the fourth postpartum day. The ischemic syndrome was followed by aneurysmal dilatation of the left ventricle and progressive heart failure that necessitated cardiac transplantation. The patient is alive and well 3 years after the transplantation. (Am J Obstet Gynecol 1990;163:538-9.)

Key words: Coronary dissection, heart transplantation, postpartum ischemic syndrome

Coronary artery dissection without aortic involvement is a known but rare condition. Less than 60 cases have been reported in the literature. In a recent review Robinowitz et al.[1] reported that 85% of the cases occurred in women, most frequently during the peripartum or postpartum period. Coronary artery dissection in pregnancy or post partum usually appears with sudden collapse and death or with a severe ischemic syndrome. Survival has been reported only occasionally and the diagnosis has been made at autopsy. The left coronary artery is generally involved.

Case report

A 33-year-old primiparous woman was delivered spontaneously at term on July 23, 1986. Medical history was unremarkable. An electrocardiogram at the thir-

tieth week of pregnancy was normal; 4 weeks later she had a short episode of epigastric pain. On the fourth postpartum day she again experienced severe epigastric pain with posterior irradiation accompanied by profuse perspiration. The electrocardiogram revealed ST segment elevation in leads I and aVL. A gallop rhythm with a protodiastolic third sound was present. An echocardiogram showed hypokinesis of the septum and left ventricular apex. Electrocardiogram evolution indicated an acute transmural anteroseptal myocardial infarction. On day 7 an echocardiogram was consistent with a left ventricular aneurysm and hypokinesis of the apex, distal two thirds of the interventricular septum, and lateral and anterior walls. The serum creatine phosphokinase level was 2120 IU/L, and lactic dehydrogenase was 3239 IU/L. The patient was in a low output syndrome and required intravenous inotropic support. Technetium 99 radionuclide angiography 3 weeks later disclosed left ventricular dilatation with an apical aneurysm and interventricular septal and lateral wall hypokinesis. After referral to Niguarda Hospital the patient underwent heart transplantation in October 1986. She is symptom-free 36 months after operation. She receives low-dose triple-drug therapy (cyclosporine, azathioprine, and prednisone) and leads a normal life.

The heart excised at transplantation weighed 280 gm. Myocardial tissue of the inferior two thirds of the left ventricular anterolateral and anteroseptal walls was replaced by fibrotic scar tissue. The left main and anterior descending branches of the left coronary artery showed a thickened intima but without critical stenosis. There was an organized dissection of the media, with new lumen formation filled by coagulated blood originating 6 mm above the coronary ostium for a length of approximately 18 mm. At histologic examination degenerative changes were present. No periadventitial inflammation was observed. The circumflex branch and the right coronary artery were normal. Pathologic findings were consistent with a large anteroseptal myocardial infarction caused by aneurysmal dissection of the left main and left anterior descending coronary artery, with partially restored vessel patency and organization of the dissected vascular wall.

Comment

Spontaneous primary coronary artery dissection is a rare condition that is most frequently observed in the peripartum period. In almost all cases reported, the medical history was unremarkable and pregnancy and delivery were uncomplicated. It has been suggested that coronary artery dissection may be a result of vasculitis. Localized periadventitial inflammation adjacent to the lesions primarily composed of eosinophilic infiltrate has been reported[2]; however, this might be a secondary reaction rather than a primary lesion. It is more likely that the hemodynamic changes that occur during labor and the straining of delivery may cause intimal disruption or rupture of the vasa vasorum into the medial wall. These mechanisms are probably facilitated by the vascular degenerative changes that occur in pregnancy. A mucoid medial degeneration of the aorta has been found in cases of aortic dissection during pregnancy, and in approximately 40% of cases of coronary artery dissection. None of the reported cases had clinical symptoms of coronary artery dissection immediately after delivery. Ours is only the second case reported in the first week of puerperium, whereas usually coronary artery dissection appears 14 to 90 days post partum. It might be argued that the clotting changes that occur early in puerperium can delay medial bleeding initiated at delivery.

In conclusion, coronary artery dissection is certainly a cause of myocardial infarction during puerperium at least as frequently as thrombosis or embolization. Current therapeutic strategies (fibrinolytic treatment) commonly used in myocardial infarction are entirely inappropriate in these cases. Thus particular caution must be used to distinguish thrombosis from dissection in peripartal myocardial infarction. Early coronary angiography should be performed when necessary to assist in the choice of medical or surgical intervention. To our knowledge this is the first case of postpartum coronary artery dissection successfully treated by heart transplantation.

Induction of labor with mifepristone (RU 486) in intrauterine fetal death

D. Cabrol, MD,[a] C. Dubois, MD,[b] H. Cronje, MD,[c] J. M. Gonnet, MD,[d] M. Guillot, MD,[e] B. Maria, MD,[f] J. Moodley, MD,[g] J. F. Oury, MD,[h] J. M. Thoulon, MD,[i] A. Treisser, MD,[j] D. Ulmann, MD,[k] S. Correl, MS,[b] and A. Ulmann, MD[b]

In a double-blind controlled multicentric study involving 94 patients with an intrauterine fetal death, we investigated the efficacy and tolerance of mifepristone (RU 486), a steroid compound that antagonizes progesterone action at the receptor level. Success of treatment was defined as the occurrence of fetal expulsion within 72 hours after the first drug intake. Mifepristone treatment (600 mg per day for 2 days) was considered to be effective in 29 of 46 patients (63%). There were only eight successes in 48 patients (17.4%) in the placebo group ($p = 0.001$, χ^2 test). Tolerance was good in the mifepristone group. In the placebo group, disseminated intravascular coagulation occurred in one woman for whom the investigator waited several weeks for spontaneous expulsion. This large double-blind controlled study provides evidence that mifepristone is of interest in the management of intrauterine fetal death. It could provide a pharmacologic alternative to the use of prostaglandins in this indication. (AM J OBSTET GYNECOL 1990;163:540-2.)

Key words: Mifepristone, intrauterine fetal death, induction of labor

Intrauterine fetal death remains a common and serious problem. The risk of complications, such as psychologic distress and disseminated intravascular coagulation, leads most clinicians to induce fetal expulsion when possible. In this respect, prostaglandins provide an effective method of inducing labor and constitute a common approach to the management of intrauterine fetal death. However, their use is limited by contraindications and side effects.

Mifepristone (RU 486, Roussel Uclaf, Paris, France) is a steroid compound that antagonizes progesterone and glucocorticoid actions at the receptor level. It has been successfully used for first-trimester abortion.[1,2] It was also shown to induce labor in an open pilot study of intrauterine fetal death.[3] However, because spontaneous labor can occur during intrauterine fetal death, a placebo controlled study was necessary to confirm this finding.

Patients and methods

This double-blind study versus placebo was designed to assess the efficacy of mifepristone for labor induction in intrauterine fetal death. The study took place in 10 obstetric and gynecology departments in France and South Africa after approval from an Independent Ethics Committee.

All inpatients who participated in the study gave written informed consent. Inclusion criteria were a gestational age >16 weeks from the last menstrual period and the absence of signs of imminent labor. Women with suspected disseminated intravascular coagulation were excluded from the study. The number of women to be included was calculated to be 100 (50 per group), assuming an expulsion rate of 25% in the placebo group and of 80% in the mifepristone group, for a type 1 and a type 2 error of 0.05.

The patients were randomly allocated to receive treatment with either mifepristone 600 mg (200 mg three times a day) or placebo for 2 days. Treatments were supplied individually packed by Roussel Uclaf after a balanced randomization list was obtained by the method of random permutations. Success was defined by the occurrence of fetal expulsion within 72 hours after the first drug intake. Even in this case, the patients underwent uterine revision. If expulsion had not occurred within 72 hours, intrauterine fetal death was managed according to standard procedure for each center.

Tolerance was evaluated by general and gynecologic examination twice daily and by the following laboratory tests performed before treatment and at expulsion (or at the latest, 72 hours after the first drug intake): hemogram, prothrombin, partial thromboplastin time, serum glutamate oxaloacetate transaminase, serum glutamate pyruvate transaminase, γ-glucose tolerance, plasma glucose, and creatinine levels. Statistical analysis was performed with the χ^2 test and the Fisher exact test. The p values below 0.05 were considered significant.

Results

A total of 94 women were included in the study (48 in the mifepristone group, 46 in the placebo group). Table I shows that the groups were comparable in terms of age and obstetric parameters. In addition, pretreatment progesterone levels did not differ significantly.

The cause of fetal death was determined in only 30 women: fetal death was attributed to maternal pathology in 15 cases and to fetoplacental abnormality in 15 cases.

For efficacy analysis, two women from the mifepristone group were excluded because they did not meet the inclusion criteria.

Labor occurred within 72 hours after the first drug intake in 29 of 46 patients (63%) in the mifepristone group and in only eight of 46 cases (17.4%) in the placebo group ($p < 0.001$).

Clinical tolerance was good. No significant modifications of blood pressure or heart rate were observed in either group. Intercurrent symptoms were reported with comparable frequency in both groups (Table II).

In the mifepristone group, minimal or moderate uterine bleeding was reported three times but did not require blood transfusion or hemostatic procedure. In the placebo group, disseminated intravascular coagulation occurred in a woman who had not expelled the fetus within 72 hours. Because this woman had a contraindication to the use of prostaglandins, the investigator decided to wait for a spontaneous expulsion. This woman was successfully treated with heparin therapy and underwent uterine revision.

Laboratory data were available for 70 women. The main results are given in Table III. There were no significant variations for any parameters in either treatment group. Furthermore, no abnormal values for hepatic enzymes were found after treatment.

Comment

This large double-blind study confirms that, as shown in a preliminary trial,[3] mifepristone can be useful in the management of intrauterine fetal death. Indeed, mifepristone induced labor in 63% of the patients, as compared with 17.4% in the placebo group.

The success of mifepristone in intrauterine fetal death is lower than that obtained during first-trimester pregnancy interruption.[1, 2] but much higher than that achieved in second-trimester pregnancy interruption when the fetus is still alive.[4] This last point raises the problem of the hormonal control of labor onset in these two situations.

Tolerance was good. Uterine bleeding was reported three times in the mifepristone group. The bleeding, which may have been a result of the antiprogesterone properties of the drug, was moderate and did not require blood transfusion. The only serious adverse event

occurred in the placebo group in which a woman suffered from a disseminated intravascular coagulation. It is noteworthy that this woman had a contraindication to the use of prostaglandins and that the investigator waited several weeks for a spontaneous expulsion. This underlies the well-known risk of a prolonged therapeutic abstention.

Biologic tolerance was also satisfactory. There was no significant difference between the placebo and the treatment group. However, this must be considered cautiously because laboratory data were available in only 74% of the cases.

Prostaglandins are commonly used in the treatment of intrauterine fetal death. The success rate with prostaglandins ranges from 91%[5] to 100%.[6] Nevertheless, prostaglandins are not well tolerated and their use is limited by classical contraindications (e.g., hypertension, scarred uterus). Mifepristone could be the treatment of choice in these cases. Moreover, data obtained in first- and second-trimester pregnancy interruption[7,8] indicate that mifepristone enhances uterine sensitivity to prostaglandins, thereby allowing the use of lower doses of the latter to induce abortion. It is likely that this synergistic effect is useful for the management of intrauterine fetal death but it requires further demonstration.

We thank Patricia Sraiki for her assistance.

Mifepristone (RU 486) failure in an ovarian heterotopic pregnancy

Jay H. Levin, MD,[a] Maria Lacarra, RN,[b] Gerrit d'Ablaing, MD,[c] David A. Grimes, MD,[b] and Michael Vermesh, MD[a]

Los Angeles, California

A patient treated with mifepristone (RU 486), which successfully induced abortion of an intrauterine pregnancy, was discovered to have a heterotopic ovarian pregnancy resistant to this antiprogesterone. The ovarian pregnancy was removed with operative laparoscopy. This case demonstrates for the first time that an ovarian pregnancy may be resistant to treatment with RU 486 at a dose adequate to abort an intrauterine pregnancy. (AM J OBSTET GYNECOL 1990;163:543-4.)

Key words: Mifepristone (RU 486), antiprogesterone, heterotopic ovarian pregnancy, laparoscopy

Although the antiprogesterone mifepristone (RU 486) has been used successfully as an abortifacient in early gestation, it has been reported to fail to eradicate tubal ectopic pregnancy.[1, 2] We report the failure of mifepristone to eradicate an ovarian heterotopic pregnancy in a woman with a coexisting intratuerine and ovarian pregnancy. This ovarian pregnancy was managed successfully by operative laparoscopy.

Case report

A 27-year-old primigravid woman was seen at the Los Angeles County/University of Southern California Medical Center 39 days after her last menstrual period and requested induced abortion with mifepristone. Initial screening by the institutionally-approved protocol included a normal physical examination, a serum β-subunit human chorionic gonadotropin (β-hCG) level of 4950 mIU/ml, and transvaginal ultrasonographic identification of a 14 mm intrauterine sac with a corpus luteum on the left ovary. The next day (day 1), after written informed consent, she received 600 mg mifepristone orally. On day 4 she received 50 μg 15-methyl prostaglandin $F_{2\alpha}$ intramuscularly, also per protocol. Vaginal bleeding began on day 3 and decreased to light spotting on day 12. Serial β-hCG levels were monitored as follows: day 0, 4950; day 1, 7300; day 4, 5760; day

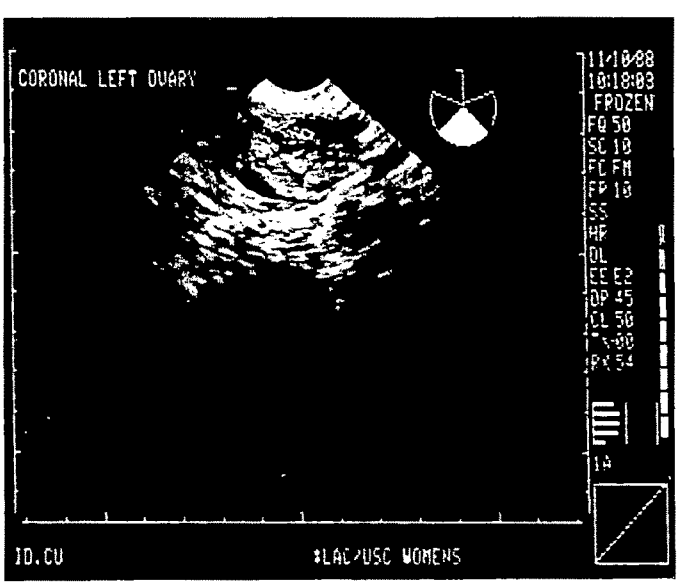

Fig. 1. Transvaginal ultrasonographic image of 12 × 4 mm irregular left ovarian cyst.

8, 1120; and day 14; 1690 mIU/ml. On day 14 the examination result was normal. Another examination on day 19 was also normal, but the β-hCG level had risen to 1930 mIU/ml. Curettage was performed on day 21 for removal of presumed retained products of conception. Vaginal ultrasonography before the curettage revealed no intrauterine sac, no corpus luteum, and no identifiable adnexal abnormality.

Although no villi were identified grossly or microscopically, the curettings contained intermediate trophoblastic tissue positive for keratin and placental lactogen, consistent with the diagnosis of residual intrauterine products of conception.[3] In addition, retrospective measurements of serum progesterone from day 0 and day 1 were 27.4 and 32.5 ng/ml, further corroborating the initial presence of an intrauterine pregnancy.[4]

After the curettage β-hCG levels decreased to 1180 mIU/ml (day 25) but then rose to 1840 mIU/ml (day 29). Repeat vaginal ultrasonography on day 29 revealed a flattened 12 × 4 mm irregular left ovarian cyst (Fig. 1). An ovarian ectopic pregnancy was suspected. Still asymptomatic, the patient was scheduled for laparoscopy that was performed later that day. Laparoscopy revealed normal fallopian tubes (including normal chromopertubation) and an unruptured left ovarian pregnancy. This ectopic pregnancy was removed laparoscopically after blunt dissection with grasping forceps and unipolar electrocautery of the crater deep within the ovary. The patient was discharged less than 12 hours after operation.

Microscopic examination of the tissue removed from the ovary confirmed the presence of chorionic villi with normal trophoblast. The patient recovered completely with β-hCG levels that decreased to 82 mIU/ml and then to undetectable levels by postoperative days 7 and 21, respectively.

Comment

The discovery of this ovarian pregnancy resistant to administration of mifepristone and prostaglandin supports previous findings that ectopic trophoblastic tissue may persist after such treatment. We believe that this case represents the first instance of the preoperative diagnosis of a spontaneously occurring, coexisting intrauterine and ovarian pregnancy in an asymptomatic patient. Finally, operative laparoscopy provided effective operative management of this early unruptured ovarian ectopic pregnancy.

The impact of a quality assurance process on the frequency and confirmation rate of hysterectomy

Joseph C. Gambone, DO,[a] Robert C. Reiter, MD,[b] Joel B. Lench, MD,[c] and J. George Moore, MD[a]

Los Angeles and San Diego, California, and Iowa City, Iowa

A criteria-based quality assurance process for hysterectomy was instituted at a large teaching hospital. After this process was initiated, the overall frequency of hysterectomy decreased by 24%, $p < 0.001$. Significant reductions were seen in hysterectomy rates for the following indications: chronic pelvic pain (77%, $p < 0.0001$), recurrent uterine bleeding (46%, $p < 0.001$), preinvasive disease of the uterus (55%, $p < 0.005$), and severe infection (70%, $p < 0.025$). Adenomyosis was the single indication for which an increase in hysterectomy rate was observed. This increase, however, was completely reversed during the last 2 years of the study. This quality assurance process also resulted in a significant increase in the histologic verification rate (i.e., 82% vs 93%, $p < 0.001$). These observations suggest that using such a criteria-based process can reduce the number of hysterectomies performed and improve the accuracy of the preoperative diagnosis. (Am J Obstet Gynecol 1990;163:545-50.)

Key words: Hysterectomy indications, quality assurance

The incidence of hysterectomy in the United States peaked in 1975 when an estimated 725,000 such procedures were performed. Since 1980 the estimated annual number (about 650,000) and rate of the procedure have not changed significantly.[1] Until recently, this figure was more than twice that reported in some Western European countries and currently remains one third higher.[2, 3] Regional rates for hysterectomy in the United States vary significantly, with rates highest in the South and lowest in the Northeast.[4, 5]

The lack of consensus concerning the acceptability of various indications for hysterectomy complicates efforts to determine which procedures are clearly appropriate. In addition, listing multiple indications for hysterectomy leads to confusion when others attempt to understand the primary reason for the procedure. Few reliable studies have been done that provide objective justification for many of the generally accepted indications for hysterectomy. One recent study reported that in 48% of hysterectomies reviewed, accuracy of the preoperative diagnosis could not be evaluated.[6] This difficulty arises because many appropriate indications for hysterectomy are not expected to be confirmed by abnormal tissue. For such indications suitable preoperative validation criteria are usually not provided.[4]

We recently reported a criteria-based quality assurance process that required the surgeon to select preoperatively a single indication for hysterectomy from a designated list of generally accepted indications.[7]

The purpose of this report is to examine the impact of this process on both the frequency and histologic verification rate of hysterectomy at a large military teaching hospital.

Methods

During the study period, from January 1984 through December 1987, surgeons were required to select preoperatively a single indication for each hysterectomy performed at San Diego Naval Hospital. The study protocol was reviewed and approved by the institutional review board. The specific criteria required in the preoperative evaluation of each patient have been reported previously[7] and are listed in Table I. When pathologic tissue was expected in the surgical specimen, the indication could be *verified** by the pathology report. When no pathologic tissue was expected, the indication could be *validated*† if the surgeon's preoperative note

*Used throughout this article to refer to indications that should be confirmed by histologic-pathologic examination.

†Used throughout this article to refer to indications that should be confirmed by documentation in the surgeon's preoperative note of criteria to be met before the performance of a hysterectomy.

Table I. Hysterectomy indication list with criteria

Acute condition	
A-1*	Pregnancy catastrophe (e.g., severe hemorrhage)
A-2	Severe infection (e.g., ruptured tuboovarian abscess)
A-3*	Operative complication (e.g., uterine perforation)
Benign disease (pathologic tissue expected)	
B-1	Leiomyoma
	a. Symptomatic (e.g., bleeding, pressure)
	b. Asymptomatic (>12 wk size, confuses adnexal evaluation)
B-2	Endometriosis (distinct endometriosis, unresponsive to hormone suppression or conservative surgery)
B-3	Adenomyosis
B-4	Chronic infection (e.g., recurrent pelvic inflammatory disease)
B-5	Adnexal mass (e.g., ovarian neoplasm)
B-6	Other (operator-defined, criteria specified)
Cancer or significant premalignant disease	
C-1	Invasive disease of reproductive organs
C-2	Significant preinvasive disease of uterus (high-grade squamous intraepithelial lesion or adenomatous hyperplasia of endometrium with cellular atypia)
C-3	Cancer of adjacent or distant organ (gastrointestinal, genitourinary, or breast cancer)
Discomfort (no pathologic tissue expected)	
D-1*	Chronic pelvic pain (negative laparoscopy and nonsurgical treatment attempted)
D-2*	Pelvic relaxation (symptomatic)
D-3*	Stress urinary incontinence (positive urodynamic workup)
D-4*	Recurrent uterine bleeding (unresponsive to hormone regulation and curettage—normal-sized uterus)
D-5*	Other (operator-defined, criteria specified)
Extenuating circumstances (not specifically indicated but possibly justified—requires preoperative peer review)	
E-1*	Sterilization (extenuating circumstances)
E-2*	Cancer prophylaxis (e.g., recurrent high-grade squamous intraepithelial lesion after cone biopsy or persistent adenomatous hyperplasia of endometrium without atypia)
E-3*	Other—listing extenuating circumstances

*Denotes indications where pathologic tissue is not expected to confirm the preoperative diagnosis.

documented that certain criteria had been satisfied. After the quality assurance process was initiated, frequent feedback regarding the rates of verification and validation of preoperative diagnoses was provided to medical staff members. This information was updated at least every 6 months and made available at weekly preoperative conferences.

To compare the cumulative frequency of hysterectomy before and after the quality assurance process, the charts of all patients who underwent hysterectomy at San Diego Naval Hospital from July 1981 through December 1983 were reviewed. Before July 1981, reliable data regarding hysterectomy indications were not available. The listed indication for each hysterectomy was determined. During this control period there was no designated list from which a specific indication for each hysterectomy could be selected. In those instances when more than one indication was listed, the first indication was assumed to be the primary one. These hysterectomies with multiple indications accounted for 92 (14%) of the 657 hysterectomies performed during this control period. The number of hysterectomies performed in each year of the study and control periods and the number of admissions to the gynecology service for the same years were tabulated. The cumulative frequency of hysterectomy was calculated by dividing the number of hysterectomies by the number of admissions to the gynecology service during the same time period and multiplying by 100. This is expressed as a rate per 100 gynecology admissions.

Review of admission policy, age, race, and active duty military status during both periods revealed no factors that might have caused significant differences in the demographic profile of patients admitted to the gynecology service. Also, the number of health-care providers, as well as the number of available operating rooms, was unchanged during both periods. Before initiating the quality assurance process in 1984, operating surgeons were unaware of the plans to implement such a program. A military hospital, as a study institution, is unique because the catchment areas for patient eligibility are well defined and policies regarding patient care are more constant than for other types of hospitals.

Statistical analysis of the hysterectomy rates by indication during each of the two periods was performed with either χ^2 or two-tailed Fisher's exact test as appropriate. A confidence level of $p < 0.05$ was considered significant. To assess whether any observed change in the cumulative frequency of hysterectomy was due to

the quality assurance process or was simply the result of an unrelated gradual decrease over the 78-month time frame (control and study periods combined), a time series analysis[8] of the quarterly rates of hysterectomy during the control period was compared with a time series analysis of the quarterly rates during the study period.

Results

A total of 657 hysterectomies were performed between July 1981 and December 1983, and 748 were performed between January 1984 and December 1987. The average quarterly admission rate for the 30-month control period, when there were 4860 admissions to the gynecology service, was 487 ± 49. This rate did not differ significantly from that of the 48-month study period (455 ± 80) when there were 7280 admissions ($p = 0.56$).

A significant reduction ($p < 0.001$) in the overall hysterectomy rate was observed during the study period (Table II). Significant decreases in the rates of hysterectomy for chronic pelvic pain ($p < 0.0001$), recurrent uterine bleeding ($p < 0.001$), preinvasive disease of the uterus ($p < 0.005$), and severe infection ($p < 0.025$) were observed during the study. Adenomyosis was the only indication for which a statistically significant increase in the hysterectomy rate was observed ($p < 0.001$).

After we instituted the quality assurance process, a significant decrease in the hysterectomy rate was seen for those indications where pathologic tissue was not expected (6.5 vs 3.5 per 100 gynecology admissions, $p < 0.001$). This group of indications consisted of pregnancy catastrophe, operative complication, chronic pelvic pain, stress urinary incontinence, recurrent uterine bleeding, and those elective hysterectomies done with extenuating circumstances. Also observed was a significantly higher percentage of verifiable indications that were confirmed after initiation of the quality assurance process (282 of 345 or 82% vs 459 of 494 or 93%, $p < 0.001$). Table III lists these indications with verification rates before and after the quality assurance process.

Linear regression analysis of the quarterly hysterectomy rates before and after initiation of the quality assurance process are shown in Fig. 1. This time series analysis of the rates indicates no significant upward or downward trend within either the control period or the

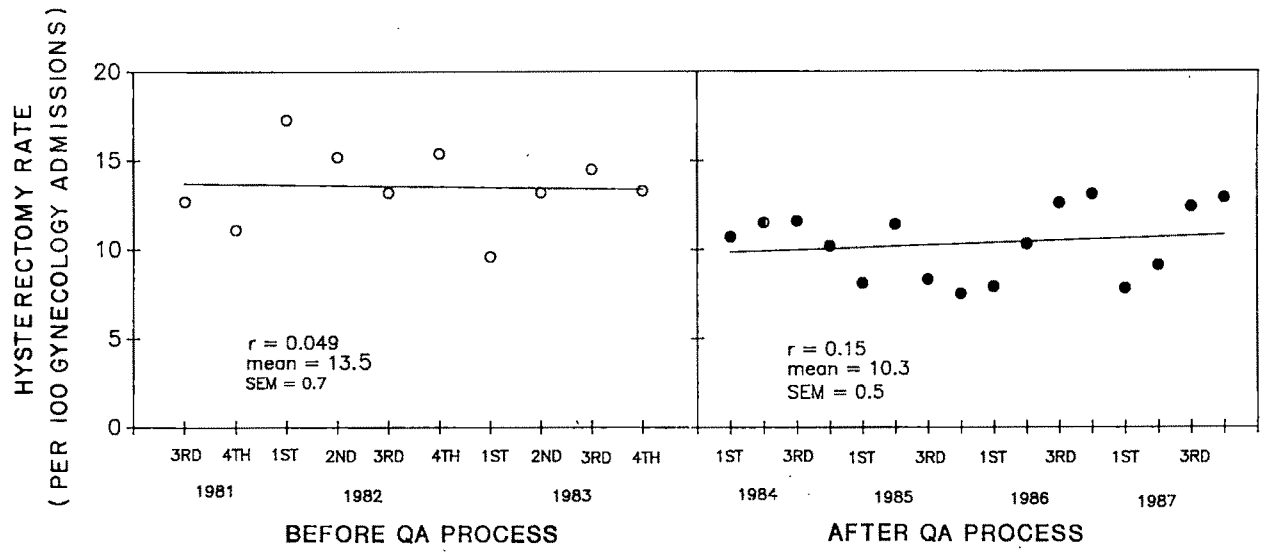

Fig. 1. Time series analysis of quarterly hysterectomy rates before *(open circles)* and after *(closed circles)* the quality assurance process. The significant decrease in mean cumulative incidence (13.5 vs 10.3, $p < 0.001$) is not a gradual decline over time but rather a discrete change that occurs after institution of the quality assurance process in January 1984.

Table III. Number and percent of surgical specimens by indication for hysterectomy that were confirmed by pathologic tissue (verified) before and after the quality assurance process*

†χ^2 or two-tailed Fisher's exact test as appropriate.

study period even though the overall rate of hysterectomy was significantly lower during the entire study period (10.3 per 100 admissions) than during the entire control period (13.5 per 100 admissions). These data suggest that the observed decrease in overall hysterectomy rate was the result of the quality assurance process rather than the result of a gradual downward trend over time.

Comment

The basis for the relatively high incidence of hysterectomy in the United States has been scrutinized by a variety of medical and nonmedical authorities.[9-11] Regional differences in the incidence of this procedure have been cited as evidence that the overall number could be significantly reduced.[4,5] One study has shown that requiring the use of a generally accepted list of indications for hysterectomy can result in a decrease in its incidence.[12] This study supports this concept by demonstrating a 24% reduction in the incidence of hysterectomy after institution of a criteria-based quality assurance process.

By requiring the surgeon to select a single indication the process was easily monitored and the reason for individual hysterectomies was clarified. Listing multiple indications has been recognized previously as a source

of confusion and may encourage the practice of adding together several insufficient indications to justify the surgery.[13]

Clarification of the reasons for surgery and feedback of information about therapeutic outcome to both physicians and the public have been reported to reduce both the incidence and the regional variation of several surgical procedures including hysterectomy.[14, 15]

Comparison of hysterectomy rates before and after initiation of the quality assurance process shows that significant decreases occurred for several of the more ambiguous and controversial indications.[6, 7, 13] Chronic pelvic pain accounted for the largest decrease (77%) in the rate of hysterectomies performed. The requirement of prior diagnostic laparoscopy and the option of alternative management in a multidisciplinary chronic pelvic pain clinic, which was established as part of the quality assurance program, may have reduced the need for hysterectomy as other treatment modalities, such as psychiatric and pharmacologic therapy, were found to be effective alternatives.

Recurrent uterine bleeding was another indication for which a substantial decrease in hysterectomy incidence was noted. The requirements of a trial of hormonal therapy and at least one uterine curettage may explain the 46% decrease in hysterectomy rate for this indication. Long-term follow-up will be required to ascertain if these alternative therapies done in cases of chronic pelvic pain and recurrent uterine bleeding merely delayed, rather than eliminated, the performance of a hysterectomy.

The 55% decrease in the rate of hysterectomy for treatment of preinvasive disease of the uterus was probably caused by the fact that after initiation of the quality assurance process, only "significant" premalignant lesions of the cervix or the endometrium, such as severe cervical dysplasia or adenomatous endometrial hyperplasia with cellular atypia, were considered to be acceptable indications.

Adenomyosis was initially selected more frequently as a preoperative indication for hysterectomy after establishing the quality assurance protocol. This effect most likely occurred because the criteria for chronic pelvic pain (Table I, D-1) or recurrent uterine bleeding (Table I, D-4) required more extensive and specific preoperative evaluation than did adenomyosis. However, the rate of hysterectomy because of adenomyosis dropped significantly during the second 2 years of the study as compared with the first 2 years (0.7 vs 0.2 per 100 gynecology admissions, $p < 0.01$). Presumably this was due to the low rate of histologic verification (38%) observed and reported for this indication during the first 2 years of the study. Currently, at our institutions adenomyosis is not considered to be a reliable preoperative indication for hysterectomy.

Another important finding was the decreased frequency with which "validatable" indications (no pathologic tissue expected) were chosen during the study period (6.5 vs 3.5 per 100 gynecology admissions). This could be explained by the fact that some of the preoperative validation criteria included certain therapeutic modalities (e.g., curettage, trial of hormones, laparoscopy, and pelvic pain clinic). Many patients could have experienced symptomatic relief as a result of these alternative interventions and the need for hysterectomy could have been avoided. Again, follow-up studies will be needed to confirm this impression.

Also noted was a significant increase in the histologic verification rate after initiation of the quality assurance process. This would imply that a quality assurance program with timely feedback of information may also improve diagnostic accuracy.

We realize that improvement in the confirmation rate of the indication does not by itself provide justification for any surgery performed. Stress urinary incontinence, where abnormal uterine tissue is not expected, is an excellent example of an indication that may have been validated preoperatively for this study but for which hysterectomy is probably not a necessary component of the therapy. Recent investigations have demonstrated similar therapeutic outcomes when urethropexy was performed without hysterectomy.[16, 17]

Long-term outcome for each indication for hysterectomy should be compared to alternative forms of therapy, both surgical and nonsurgical, with respect to efficacy, safety, and cost.[18] We feel that the consistent application of a quality assurance process such as this could very likely encourage the evolution of a standardized indication list with concomitant confirmation criteria for each indication. This would greatly facilitate the comparison of the effectiveness and appropriateness of the various therapies for each indication. As information is collected and analyzed, it may be logical to consider eliminating certain indications from the list, as in the case of adenomyosis and urinary stress incontinence.

The results of this study suggest that a quality assurance process that required the selection of a single preoperative indication from a standardized list of indications, and which establishes specific preoperative validation criteria for those cases when pathologic tissue is not expected, may be a substantial factor in reducing the frequency of hysterectomy. Because this study is a single-hospital-based analysis with the number of gynecology admissions used as the denominator to calculate the rate of a procedure, these changes could have been influenced by differences in types of patients admitted or surgeons operating during the two periods that were analyzed. These differences are less likely to have occurred at a stable military hospital, however,

and it is unlikely that the substantial (24%) decrease could be explained on this basis alone.

The results of this study also show that frequent feedback at weekly preoperative conferences of confirmation rates does result in an improvement in the diagnostic accuracy of the preoperative diagnosis (indication) for hysterectomy. This finding is not likely to have been influenced by the methods of this study.

Retropubic long-needle suspension procedures for stress urinary incontinence

R. Edward Varner, MD
Birmingham, Alabama

A brief review of the Pereyra and the Stamey procedures and their modifications, including success rates and potential problems, is presented. A new modified technique is described that has potential advantages of ease, rapidity, less dissection, and less blood loss than may be seen with the modified Pereyra procedure and less chance of foreign body reaction than may be seen with the Stamey procedure. Twenty patients with significant stress urinary incontinence (14 with concurrent severe pelvic relaxation) underwent the procedure with an 80% cure plus 5% significant improvement rate noted 12 to 39 months after operation. All failures occurred in patients who were obese and involved apparent suture pull-through. Complications were minimal. Suggested causes for failures are discussed. (Am J Obstet Gynecol 1990;163:551-7.)

Key words: Stress urinary incontinence, Pereyra procedure, Stamey procedure, Raz procedure, Gittes procedure

A number of gynecologists and urologists have promoted a variety of procedures for anatomic stress incontinence that involve the retropubic passage of long suture-loaded needles. These procedures have been advocated because of their "relative ease," presumed shorter operative times, and lower perioperative morbidity than the abdominal retropubic suspensions, and for their potential use with vaginal repair procedures in patients with significant pelvic relaxation and concurrent severe stress urinary incontinence.

In 1959, 10 years after the first Marshall-Marchetti-Krantz description was published, Pereyra[1] described his first procedure that used a specially designed two-pronged needle, stainless steel wire, and a small suprapubic abdominal incision down to but not including the rectus fascia. Subsequent modifications of the procedure have included blunt retropubic dissection and the use of a pubourethral helical stitch of permanent suture to prevent technique failure caused by suture pull-through.[2,3] Stamey,[4-6] Raz,[7] Leach and Raz,[8] Muzsnai et al.[9], and others[10-12] have reported other modifications or somewhat similar procedures to both simplify stitch placement and to better secure the elevating sutures. Reported cure rates have varied with technique and with the type and duration of patient follow-up (Tables I and II). Although complications appear to be rare with the Stamey procedure, the incidence of delayed suture reaction or chronic pain in the area of the periurethral buttress appears to be significant. In addition, the operative times and perioperative blood loss with these modified Pereyra procedures may be comparable to those observed with abdominal approaches. Recently Gittes and Loughlin[18] described a more simplified procedure in which no vaginal incision and only stab suprapubic incisions are made. Although the initial success rate of this procedure may be acceptable, it has been suggested that long-term success will be poor as a result of suture pull-through.

Several further modifications of these techniques have been made after consideration of the actual and theoretical advantages and disadvantages of the procedures.

Material and methods

Operative technique. A transverse incision approximately 5 cm in length is made 2 cm above the symphysis pubis to the rectus fascia. An area of the fascia approximately 3 × 5 cm is cleaned. If an anterior colporrhaphy is to be performed for a symptomatic cystocele, the anterior vaginal midline incision is stopped 2 cm proximal to the bladder neck. A transverse vaginal incision is made through the submucosa 1 cm distal to

the bladder neck. Scissors are then inserted with spreading deep to the vaginal submucosa (paravaginal fascia) on each side of the bladder neck to dissect two areas 1.5 to 2 cm diameter between the paravaginal fascia and the pubourethral connective tissue (Fig. 1). The paravaginal connective tissue and vaginal submucosa is then incorporated in two to three needle bites with a no. 1 Teflon-coated nylon suture (1 Ti-cron [DT-19], Davis and Geck, Dansbury, Conn.) on a genitourinary type needle (Fig. 2). If the overlying pubourethral connective tissue appears dense, it is incorporated in one of these bites. Suture placement should always be lateral to the urethral-vesical junction. Preoperative estrogen administration (preferably for 3 months) to improve tissue strength appears to be important in patients with vaginal atrophy. If the patient

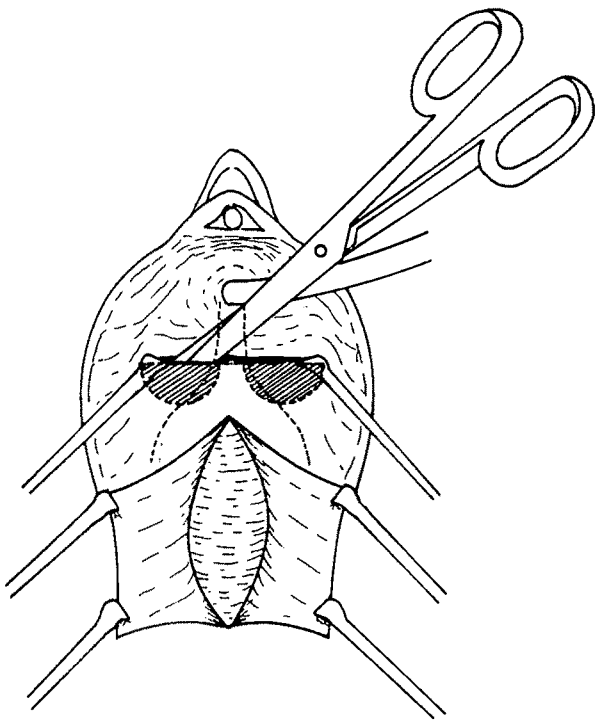

Fig. 1. Modified procedure. Dissection is performed deep to the paravaginal connective tissue, bilaterally, through a transverse incision 1 cm distal to the bladder neck.

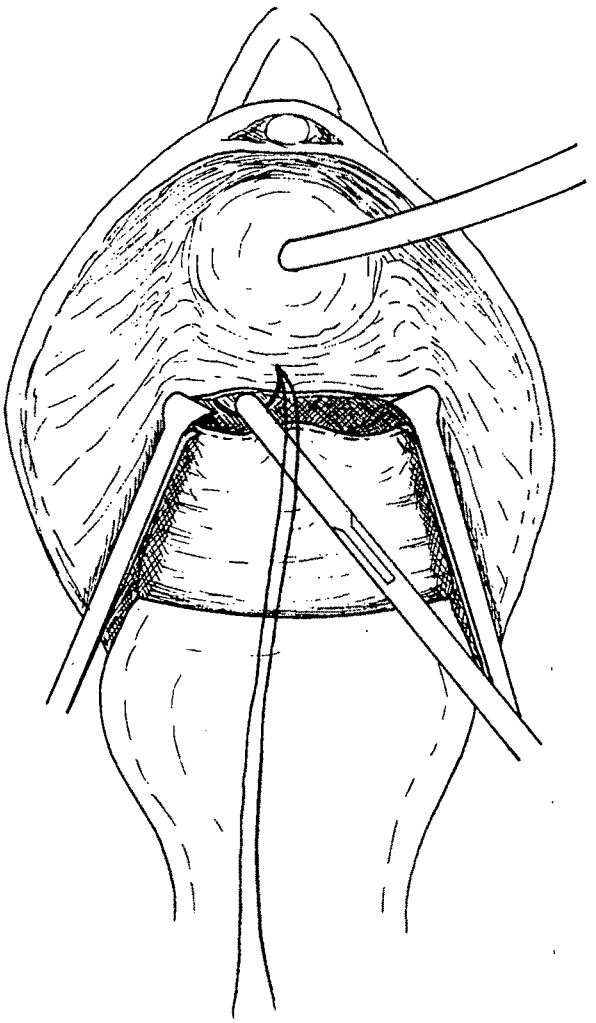

Fig. 2. Permanent no. 1 nylon sutures (three needle bites) are placed into the paravaginal connective tissue (often full-thickness) lateral to the bladder neck.

has had a previous retropubic procedure or has evidence of anterior vaginal or bladder neck scarring, more extensive lateral and subpubic dissection is performed to mobilize the bladder neck, proximal urethra, and underlying vagina to avoid excess tension at the suture sites.

A Stamey needle is then loaded with the free end of the suture with its origin closest to the bladder neck. It is placed an estimated 1 cm lateral to the Foley bulb just proximal to the urethral-vesical junction. After complete bladder emptying is noted, the needle is then directed anteriorly and advanced until the resistance of the symphysis pubis is met, then shifted anteriocephalad to pass retropubically through the cleaned area of rectus fascia where the suture is removed from the needle (Fig. 3). The needle is then removed and reloaded with the lateral free suture end. It is placed 1.5 cm lateral and distal to the first and advanced likewise retropubically to the fascia 1 to 2 cm lateral to the first suture. The same procedure is done on the opposite side of the bladder neck.

At this point in the procedure a 70-degree cystoscope is placed transurethrally, and, while filling, the bladder is examined for evidence of suture. If a perforation is noted, the suture is removed, the bladder is emptied, and the suture is replaced. Before removal of the cystoscope, bladder neck closure is observed by elevating the suture ends above the abdominal incision.

Before elevation of the retropubic sutures the anterior colporrhaphy is completed, the vaginal incisions are closed, and a suprapubic catheter is placed. The sutures are then elevated and secured above the rectus fascia (Fig. 4). When the rectus fascia is noted to be thin and attenuated, a small Gore-Tex patch (W. L. Gore & Associates, Inc., Elkton, Md.) is used above the fascia to prevent potential suture pull-through. The amount of elevation of the bladder neck is a matter of judgment and depends on the severity of the defect, cystoscopic evidence of bladder neck closure with suture elevation, and whether leakage can be produced by suprapubic pressure on the full bladder. After tying

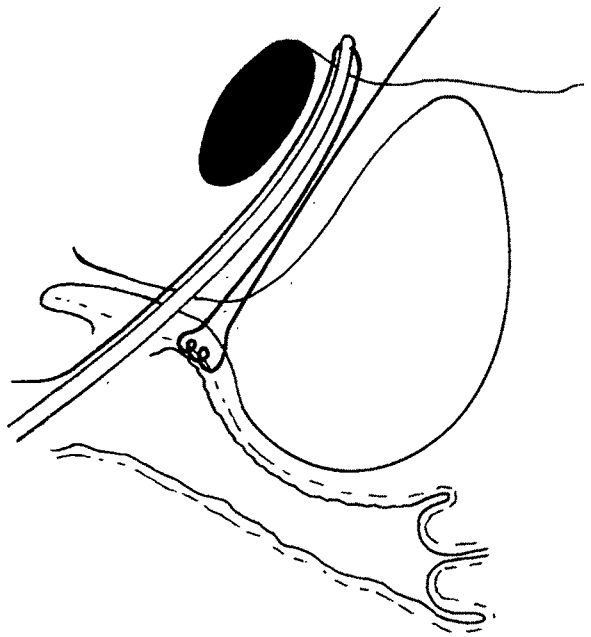

Fig. 3. The suture-loaded Stamey needle is passed twice on each side of the bladder neck through the vaginal incision, pubourethral connective tissue, retropubic space, then rectus fascia.

the sutures the abdominal wall incision is then thoroughly irrigated and closed.

Prophylactic antibiotics are given perioperatively and estrogen therapy is continued postoperatively in menopausal patients.

Evaluations and patient characteristics. This procedure was performed on 20 patients between September 1985 and December 1987. The author was the primary surgeon for all of the cases. Patient evaluation before surgery included (1) history and physical examination (a thorough urologic history and pelvic examination were performed noting pelvic relaxation and bladder neck descent with Valsalva in the lithotomy and standing position and perineal neurologic function), (2) urinalysis, urine culture, or both, (3) urodynamic assessments that included a flow study, residual urine measurements, resting urethral pressure profile with a dual-microtip transducer catheter, water cystometrics, stress tests, and voiding studies, (4) dynamic urethroscopy, and (5) voiding cystourethrograms in two patients with unusual symptoms.

Patients ages ranged from 38 to 71 years (mean, 59; median, 56). Fifteen of the patients were menopausal and 12 of these received preoperative estrogen therapy. Twelve patients were multiparous and there were no nulliparous patients.

All patients related urine loss with coughing, laughing, and physical activity. Only five of the 20 patients did not use protective clothing or pads and each of these had third- or fourth-degree cystoceles and experienced significant stress leakage when the prolapse was reduced. One patient had constant leakage, a very low-pressure urethra, and declined a sling procedure. Past history revealed six patients with failure of previous surgery for stress incontinence. Fourteen patients had previous hysterectomies. Medical problems included three patients with chronic obstructive pulmonary disease, three with severe arthritis, and one with coronary artery disease after coronary bypass. Nine of the patients were smokers. Patient weights ranged from 104 to 250 pounds (mean weight, 166 pounds; median, 167 pounds). Seventy percent of the patients could be defined as obese (>120% of their ideal body weight by Metropolitan Life Tables, 1959); 14 patients weighed >145 pounds, eight weighed >180 pounds, and three weighed >220 pounds. Fourteen patients (70%) had concurrent pelvic relaxation, four with either total vault prolapse or procidentia. Six of the patients (three elderly and two morbidly obese) required an incontinence procedure alone and chose the procedure over a retropubic approach.

Bladder evaluations revealed that all patients had positive stress tests before capacity and urodynamic evidence of stress incontinence. Five patients had peak urethral pressures <40 mm Hg (one with 10 mm Hg). Three patients had evidence of instability on cystometric evaluation; two had detrusor contractions only after positive stress tests. Eleven patients with cystoceles had intermittent flow on voiding study.

The procedure on all 20 patients was that described with the addition of anterior and posterior repair with sacrospinous vault suspension in three cases, vaginal hysterectomy with anterior and posterior repair (one with sacrospinous suspension) in three cases, anteroposterior repair in six cases, one anterior repair, and one posterior repair.

Telephone follow-up was obtained on all patients in December 1988 (12 months to 39 months after operation). All patients who complained of any leakage and six of the patients who reported having no leakage with stress underwent urodynamic evaluation after December 1988.

Results

Sixteen patients (80%) reported complete relief of leakage with stress. Six of these 16 underwent examination and urodynamic evaluation that confirmed operative success. One of the 16 related rare leakage with urgency when her bladder was full and had detrusor instability confirmed urodynamically before and after

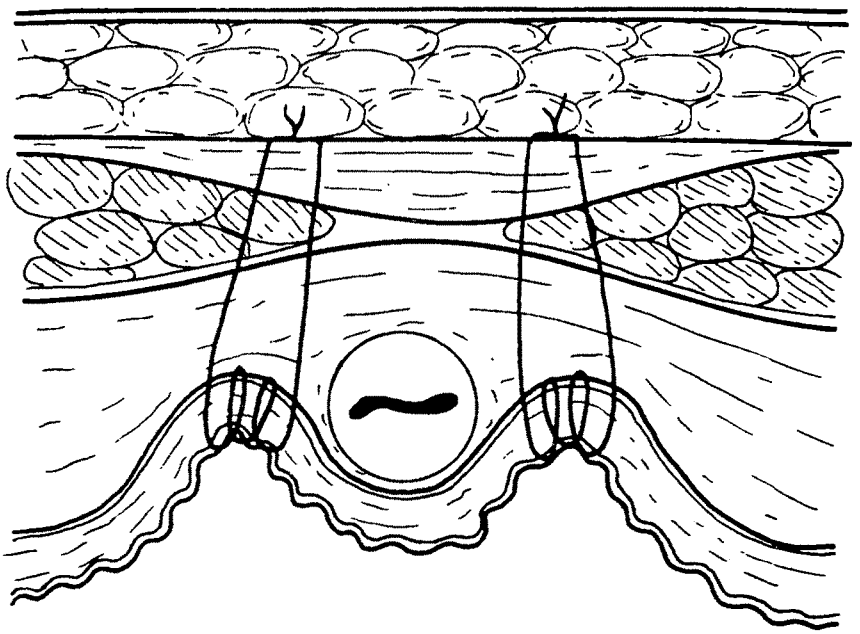

Fig. 4. After cystoscopy, the sutures are secured to the rectus fascia, thus elevating the urethrovesical junction.

operation. One patient whose weight increased from 220 to 280 pounds since operation in June 1986 had improvement but had some recurrence of stress incontinence beginning 1 year after operation. The overall cure and improvement rate was 85%. No failures occurred in patients who had undergone previous operation for stress incontinence.

The procedure failed in three patients (recurrence of stress incontinence) at 4 weeks, 4 months, and 14 months after operation. All three had recurrence of bladder neck descent, positive stress tests, and positive dynamic urethral pressure profiles when evaluated. All were obese (189, 228, and 250 pounds). The patient with early failure weighed 189 pounds, was a heavy smoker, had an atrophic vagina at the time of operation, and resumed manual work 4 weeks after operation.

Complications included one small subcutaneous hematoma, one retropubic hematoma responsible for a four-point hematocrit drop that did not necessitate transfusion, three postoperative urinary tract infections during suprapubic drainage, and one unilateral stitch reaction that was noted 4 months after operation. The stitch was removed and the patient has remained continent and without other symptoms. There have been no fistulas or patients with chronic retropubic pain.

Suprapubic bladder drainage was used until patients were able to empty 75% of their bladder volume with less than 75 ml of residual urine. Only three patients voided adequately within 5 days of the procedure. The median voiding time was 10 days. Two patients required 21 days; however, all related no voiding difficulty when questioned.

The hospital stays of patients who had the procedure with concurrent repairs ranged from 3 to 6 days (mean, 4.9 days; median, 5 days). The six patients who had only needle suspension procedures had hospital stays ranging from 2 to 4 days (mean, 3.1 days.) The mean stay for patients undergoing abdominal retropubic suspension at the same institution is 5.5 days.

Comment

It is generally accepted that stress urinary incontinence results from changes in proximal urethral mechanics. All known surgical procedures for this problem have devised means whereby the urethral pressure increases with increases in intraabdominal pressure. The retropubic needle suspensions that include this relatively easily performed procedure appear to effectively create this situation. The theoretical advantages of this procedure are (1) that it is performed more rapidly than either Stamey or Pereyra procedures, (2) that there is relatively less dissection and less blood loss than with a modified Pereyra procedure, (3) that the needles are placed more easily vaginally with direct observation or palpation of the bladder neck, and (4) that, as with the most recent modification of the Pereyra procedures, the paravaginal connective tissue is the pri-

mary tissue that is elevated. Because of the complete dissection of the abdominal rectus fascia suture pull-through is thought to be less of a problem than may be seen with Gittes modification.

Although abdominal approaches may be used in patients with combined significant stress urinary incontinence and pelvic relaxation, vaginal approaches with slightly shorter hospital stays and possibly lower perioperative morbidity definitely are options. Some have advocated the pubourethral stitch anterior repair for these situations; however, others[19] have found unacceptable failure rates and have recommended alternative means of elevating the bladder neck. Combined vaginal repair procedures and long-needle suspensions should be considered.

The success rates seen in this small series with somewhat short follow-up and in some of the other needle suspension series are not quite comparable to those reported with abdominal-retropubic suspensions (85% to 95%). However, some of the differences in success may be related to the type of patients who have the procedures. For instance, a greater percentage of the long needle suspension procedures may have been performed in menopausal, obese patients with medical problems in whom laparotomy might produce a higher complication rate. Clearly, obesity was a common factor in all failures in this small series. The failure rate for the women weighing over 220 pounds was 100% (0% for nine women weighing less than 180 pounds). A well-controlled comparison of approaches in both obese and patients with normal weights is needed.

Each failure in this small series was associated with recurrence of descent of the urethral-vesical junction after successful surgical elevation. Each patient was continent for a period of time after operation. It is presumed that the procedures failed because the permanent suture material pulled through or became detached from either the vaginal submucosa or the rectus fascia. It has been postulated that retropubic procedures have lower failure rates because retropubic scarring after dissection may further serve to fix the urethral-vesical junction. Factors that would seem to predispose to stitch pull-through are genital atrophy, scarring and tissue immobility, obesity, and other conditions associated with increased intraabdominal pressure and pelvic floor stress. Whether a retropubic procedure or perhaps a sling procedure is warranted in patients who have a higher risk of failure is certainly debatable.

The long-term complication rate in patients who have needle suspension procedures appears to be comparable with that seen with retropubic suspensions. The most prevalent complication appears to be retropubic pain and stitch infection or rejection. Although this problem is more prevalent in patients who have Stamey procedures with a permanent buttress material, the fact that this complication occurred in one of 20 patients in this series without buttresses remains somewhat worrisome. Subsequent experience with 20 more procedures has thus far revealed no similar problems. Postoperative urinary retention may occur for longer periods than with some retropubic procedures; however, this decreases with operator experience. Should long-term retention occur, the removal of one stitch has been shown to relieve the problem without recurrence of incontinence. Less bladder neck elevation may serve to prevent postoperative retention and decrease the potential for future stitch pull-through by decreasing the tension on the suture.

In summary, retropubic needle suspensions provide another alternative approach to the patient with anatomic urinary incontinence. The advantages of these procedures include relative ease and decreased perioperative pain and disability. Associated problems with the procedure include stitch rejection, problems associated with improper stitch placement, and failure rates that may be slightly higher than those seen with retropubic procedures. The described modified procedure offers a simple technique that can be performed rapidly with apparently little morbidity and rapid recovery. Long-term success with a greater number of patients remains to be evaluated.

Ductus arteriosus flow velocity modulation by fetal breathing movements as a measure of fetal lung development

Jim van Eyck, PhD, Karin van der Mooren, MD, and Juriy W. Wladimiroff, PhD
Rotterdam, The Netherlands

A test is needed that would accurately predict favorable neonatal lung performance in the presence of prolonged severe oligohydramnios caused by ruptured membranes so that optimal obstetric care can be provided. We propose such a test that is based on the degree of modulation of fetal ductal blood flow velocity by fetal breathing movements after maternal glucose loading. In a prospective cross-sectional study of 49 normal pregnancies (50 fetuses) between 25 and 38 weeks an exponentional increase in breathing-related ductal blood flow velocity modulation was observed with advancing gestational age, reflecting the developing pulmonary vascular bed. Fetal ductal flow velocity waveforms were also recorded in 13 cases of prolonged severe oligohydramnios after ruptured membranes before 28 weeks' gestation. Normal ductal blood flow velocity modulation values were associated with normal neonatal lung performance, whereas reduced ductal blood flow velocity modulation values were associated with pulmonary hypoplasia. Fetal breathing-related ductal flow velocity modulation appears to be a promising predictor of neonatal lung performance. (Am J Obstet Gynecol 1990;163:558-66.)

Key words: Ductus arteriosus, Doppler flow velocity, fetal breathing movements, lung development

Rupture of membranes resulting in prolonged severe oligohydramnios during the second trimester of pregnancy may result in stillbirth or severe neonatal respiratory failure as a result of pulmonary hypoplasia. However, under these circumstances fetal outcome is not uniformly poor.[1] There is therefore a need for a test to accurately predict a favorable fetal outcome so that optimal obstetric care can be provided for these particular pregnancies.

In cases of prolonged severe oligohydraminos, contradictory findings have been reported with regard to the association between fetal breathing movements and lung performance after birth. According to Blott et al.[2] the predictive value of the presence of fetal breathing movements for continuing lung growth is 100%, and the predictive value of the absence of fetal breathing movements for pulmonary hypoplasia is 100%; however, Moessinger et al.[3] reported that the observation of fetal breathing activity is not helpful in identifying those fetuses with pulmonary hypoplasia at birth.

Ductal blood flow in the fetal lamb is modulated by lung expansion.[4] This effect results from an opening of the pulmonary vascular bed with subsequent reduced shunting of right ventricular output through the ductus arteriosus. Furthermore, increased pulmonary perfusion has been established with advancing gestational age, reflecting developing pulmonary vasculature.[5] In pulmonary hypoplasia the development of fifth- and sixth-generation vessels is impaired with a resultant reduction in development of the pulmonary vascular bed.[6] Moreover, pulmonary vascular resistance is raised and is associated with medial muscular hypertrophy of lung arterioles.[6] It may be speculated that fetal breathing-related modulation of ductal flow will be reduced in this situation.

Recently a pulsed Doppler method was introduced for recording blood flow velocity waveforms in the human fetal ductal arteriosus.[7] In this study the following questions were addressed. Does breathing-related modulation of ductal flow occur in the human fetus? If so, is this modulation age dependent and is the presence of breathing-related ductal flow modulation in prolonged severe oligohydramnios caused by ruptured membranes indicative of absent pulmonary hypoplasia?

Material and methods

All women gave informed consent for the study, which was approved by the Ethics Review Board of the University Hospital. The gestational age was calculated from a reliable menstrual history and ultrasonographic measurement of fetal crown-rump length or biparietal diameter. All women were nonsmokers.

The study population consisted of two groups. The

first group represented 55 uncomplicated pregnancies with a mean gestational age of 32.3 weeks (range, 25 to 38 weeks) randomly selected at the outpatient clinic between August 1988 and March 1989 for a cross-sectional study of normal breathing-related fetal ductal peak systolic flow velocity modulation. Recordings were performed from 25 weeks of gestation because at approximately this stage there is an increase in the total number of pulmonary vessels and vasomotor activity, reflecting the developing pulmonary vasculature during the late canalicular phase of lung development.[8] Fetal breathing activity also becomes more regular.[9] Each subject was included in the study once. One woman had a twin gestation. Mean maternal age was 28.3 years (range, 18 to 42 years); maternal parity ranged from 0 to 5. No medications were prescribed. On ultrasonographic examination there was a normal amount of amniotic fluid. Measurements of the fetal biparietal diameter, upper abdominal and head circumference, and femur length revealed a normal-sized fetus without gross structural anomalies.

The second group consisted of 32 women who were admitted during the study period either from our own outpatient clinic or were referred from other centers because of premature rupture of membranes before 28 weeks' gestation. Mean gestational age was 22.9 weeks (range, 16 to 27 weeks). Fetal ductal flow velocity measurements were begun at 25 weeks' gestation. Premature rupture of membranes must have resulted in severe oligohydramnios and had to be present over a period of 3 weeks or more before delivery. Severe oligohydramnios was defined as the absence of an amniotic fluid pool of more than 1 cm, measured in two planes on ultrasound examination. Mean maternal age in this group was 27.9 years (range, 22 to 35 years); maternal parity varied from 0 to 4. Fetal biparietal diameter, upper abdominal, and head circumference revealed a normal-sized fetus without gross structural defects. In all women with premature rupture of membranes, tocolysis was established by intravenous administration of fenoterol. No corticosteroids were prescribed, and only cases with no signs of amnionitis were studied.

Fetal ductal flow velocity measurements were performed with a combined two-dimensional real-time and continuous-wave Doppler system (Diasonics CV 400). A 3.0 MHz transducer was used. The sector scanner operated at power outputs <100 mW/cm^2 in both imaging and Doppler modes by manufacturer's specifications. All women were studied while in the semirecumbent position. A longitudinal cross-section of the fetal ductus arteriosus was obtained on a short-axis view of the fetal heart parallel to the fetal spine as first described by Huhta et al.[7] The aortic arch was distinguished from the ductal arch by visualization of the carotid arteries. The cursor line was placed in the ductus near the junction of the ductus and the descending aorta. The angle of insonation was maintained below 5 degrees. On the same short-axis view, movements of the fetal thoracic wall and diaphragm reflecting breathing movements can be observed, while the Doppler flow velocity measurements in the ductus arteriosus are performed parallel to the ductal flow direction without changing the position of the transducer.

Fetal breathing activity was defined as periodic inward movements of the fetal chest wall with downward movements of the fetal diaphragm. Continuous fetal breathing was considered present when the interval between two consecutive breathing movements was <6 seconds. In the normal developing fetus, the second trimester is characterized by irregular and sporadic breathing movements. With advancing gestational age fetal breathing becomes more regular with a reduction in breathing rate,[9] whereas the percentage of time spent breathing does not differ significantly under fasting conditions.[10, 11] Fetal breathing activity is stimulated by glucose loading.[12] This breathing response increases with advancing gestational age.[13] For this reason and to obtain accurate timing of breathing-related Doppler flow measurements, it was decided to stimulate fetal breathing activity by maternal glucose administration at the onset of each study period, after normal carbohydrate metabolism had been established (postprandial capillary glucose level <7 mmol/L) and after intrauterine growth retardation had been ruled out. Assuming that the severely growth-retarded fetus is chronically hypoxemic, a sudden surge in glucose might lead to the development of metabolic acidosis and result in fetal death.[14]

In the group of patients with prolonged severe oligohydramnios, 250 ml of a 10% glucose solution (27.5 gm) was given intravenously over a period of 15 minutes. All patients already had an intravenous line in place. In cases of prolonged severe oligohydramnios the percentage of time spent breathing is not markedly altered,[15] or is even increased.[16] In the women with normal pregnancies a single dose of 50 gm of glucose was administered orally. Peak maternal glucose levels are reached approximately 10 minutes after intravenous glucose loading and approximately 60 minutes after oral glucose loading.[13] Both routes result in a comparable rise in maternal plasma glucose concentration; moreover, the incidence and fetal breathing rate are not affected differently after oral or intravenous glucose administration.[13] We therefore did not consider it ethically appropriate to use the intravenous route in the normal group. Doppler flow velocity waveform recordings in the fetal ductus arteriosus were started at the time of the expected increase in fetal breathing activity, 30 minutes after intravenous glucose adminis-

tration[15] and 2 hours after oral glucose administration[13] to the mother. The time delay between the peak of the maternal capillary glucose level and increase in fetal breathing incidence may be explained by the local excess of carbon dioxide produced by increased oxidation of glucose, stimulating the chemosensitive areas of the brain stem.[17, 18]

Maximum flow velocity waveforms were obtained over a 15-second period after a period of continuous fetal breathing activity was observed. To ensure the presence of fetal breathing activity throughout the Doppler flow velocity recording, fetal breathing movements had to still be present after completion of the recording. The blood flow velocity waveforms were recorded on videotape and approximately 30 consecutive waveforms were obtained from hard copies of each measurement. With a microcomputer (Olivetti M24, Ivrea, Italy), the difference in peak systolic velocity between two flow velocity waveforms representing the expiratory and inspiratory phase of the fetal breathing movement was calculated. The mean difference in ductal peak systolic flow velocity modulation was established from the total number of waveform recordings during breathing activity. The diastolic portion of the ductal flow velocity waveform was not evaluated because it bears no direct relationship with shunting of blood from the pulmonary artery through the ductus. All Doppler measurements were performed by one observer (K. v. d. M.). Information on fetal ductal flow velocity recordings was not made available to the clinician responsible for the obstetric management.

The diagnosis of pulmonary hypoplasia was based on a reduced lung/body weight ratio[19] (ratio <0.015 for gestational ages <28 weeks or <0.012 for gestational ages ≥ 28 weeks) established at autopsy or on combined clinical finding of (1) immediate onset of severe respiratory insufficiency after birth requiring high-pressure artificial ventilation; (2) chest radiographs demonstrating small lung volume, with the diaphragm elevated above the seventh rib, downward sloping ribs, and a bell-shaped thoracic cage; (3) clinical respiratory disease that did not conform to the classical model of hyaline membrane disease.

The number of blood flow velocity waveforms studied in the fetal ductus arteriosus in normal pregnancy is expressed as mean ± 1 SD. A scattergram for mean ductal peak systolic flow velocity modulation in relation to gestational age was developed for all women without oligohydramnios. From the data collected in normal pregnancy, the regression line as well as the 1st, 5th, 95th, and 99th percentile lines were estimated from linear regression analysis after logarithmic transformation of ductal blood flow velocity modulation. For the estimation of the regression lines it was assumed that the residual term displays a normal distribution with the mean of zero.

Results

Normal pregnancy. Poor-quality fetal ductal flow velocity signals were obtained in six of 55 normal pregnancies because of excessive fetal body movements, lateral position of the fetal spine, or technical failure of the video equipment. In the remaining 49 pregnancies (50 fetuses), a technically acceptable recording during fetal breathing activity was documented. Oral glucose loading was performed in each instance. Mean maternal capillary glucose level was 6.4 ± 1.3 mmol/L, measured 1 hour after oral glucose administration. Fetal birth weight was between the 10th and 90th percentile for gestational age[20] corrected for maternal parity and fetal sex. Neonatal lung performance was normal. The mean number of blood flow velocity waveforms studied in the fetal ductus arteriosus was 18.1 ± 6.8.

Modulation of the ductal flow velocity waveform was characterized by a momentary reduction of peak systolic velocity during the inspiration phase (Fig. 1). Regression analysis of the ductal blood flow velocity modulation data obtained from the 50 normally developing fetuses (open circles, Fig. 2) revealed an exponential increase in ductal blood flow velocity modulation with advancing gestational age; the regression equation was $\ln \Delta PV = 0.537 + 0.076 \times$ weeks with $R^2 = 0.90$, $p < 0.0001$, where ΔPV equals ductal blood flow velocity modulation. The regression equations for the 99th and 1st percentile lines were: $0.537 + 0.076 \times$ weeks $\pm 2.58 \times 0.1017$, and for the 95th and 5th percentile lines: $0.537 + 0.076 \times$ weeks $\pm 1.96 \times 0.1017$, in which 0.1017 equals the estimated standard deviation of the residual term and 2.58 and 1.96 represent the respective two-tailed 1% and 5% points of the standard normal distribution. Fig. 2 presents the regression line and the estimated four percentile lines after transformation of the variable ln ΔPV back to its normal level by using the antilog.

Prolonged severe oligohydramnios. Of the 32 women who were admitted to our hospital during the study period because of premature rupture of membranes before 28 weeks' gestation, nine were not included in the study because no severe oligohydramnios developed. Six women were removed from the study because amnionitis developed and the women were delivered within 1 week after premature rupture of membranes; three other women were delivered before 25 weeks' gestational age. One woman was removed from the study because of intrauterine growth retardation and preeclampsia necessitating use of antihypertensive drugs; thus 13 women remained for further analysis. In these 13 women mean gestational age at onset of oligohydramnios was 23.3 ± 4.1 weeks (1 SD) and mean duration of oligohydramnios was 6.8 ± 2.9 weeks (1 SD). The maximum time interval between the last Doppler flow recording and delivery was 7 days.

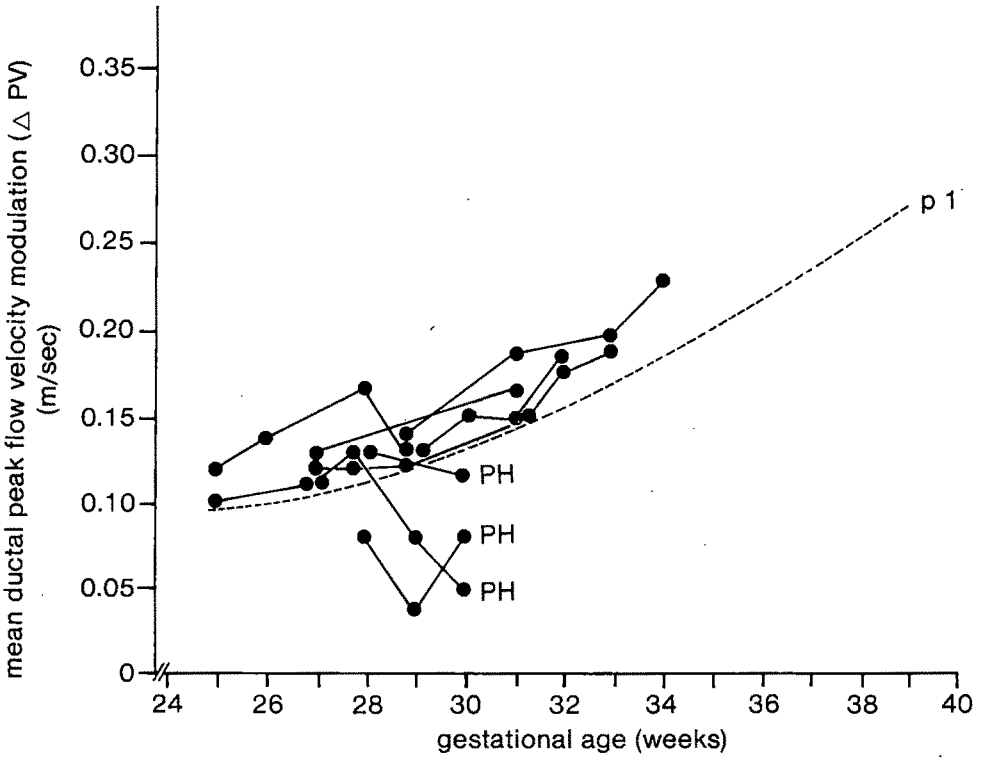

Fig. 3. The first percentile line of the normal population *(dotted line)* and the mean breathing-related ductal peak systolic flow velocity modulation relative to gestational age for nine cases of prolonged severe oligohydramnios as a result of ruptured membranes *(closed circles)* in which serial recordings were obtained. *PH,* Pulmonary hypoplasia.

Mean maternal capillary glucose level measured 10 minutes after intravenous glucose administration was 6.2 ± 2.5 mmol/L. Fetal birth weight was between the 10th and 90th percentile for gestational age,[20] corrected for maternal parity and fetal sex. Fetal heart rate always varied between 120 and 160 beats/min. Forty-one fetal ductal flow velocity recordings were technically acceptable for further analysis. Prenatal findings and fetal outcome are presented in Tables IA, IB, and II. The mean number of blood flow velocity waveforms studied in this group was 16.7 ± 7.6. Seven recordings were obtained in the absence of fetal breathing activity. In patient no. 1, absence of fetal breathing activity was documented on three different occasions despite maternal intravenous glucose administration; neonatal lung performance was normal. In patient no. 3, no fetal breathing activity could be documented in three recordings. These recordings were not preceded by intravenous glucose administration because glucose metabolism became abnormal after the first Doppler recording. Neonatal lung performance was normal in this case. Despite intravenous glucose administration we were unable to document fetal breathing activity in patient no. 9 in one of five occasions. Thirty-four recordings were obtained during fetal breathing activity (patients 2 through 13). Longitudinal follow-up was feasible in nine of 13 women with oligohydramnios and accounted for 31 ductal blood flow velocity modulation measurements (Fig. 3; closed circles). In the remaining three women only one recording was obtained. When the ductal blood flow velocity modulation data nearest to delivery were considered (mean, 3.8 days; range, 0 to 7 days; Fig. 2, closed circles), five women had ductal blood flow velocity modulation values below the 1st percentile of the reference curve. These reduced values were associated with pulmonary hypoplasia. For the remaining seven women ductal blood flow velocity modulation values were within the normal range of the reference curve and were associated with normal neonatal lung performance. For the group of women with prolonged severe oligohydramnios that resulted in pulmonary hypoplasia, the mean gestational age at the onset of oligohydramnios was 21.8 ± 4.6 weeks (1 SD) and the mean duration of oligohydramnios was 8.6 ± 2.9 weeks (1 SD). For the group of women with prolonged severe oligohydramnios with normal neonatal lung performance, the mean gestational age at the onset of oligohydramnios was 24.3 ± 3.7 weeks (1 SD) and the mean duration of oligohydramnios was 7.0 ± 2.5 weeks (1 SD). Four of five cases of pulmonary hypoplasia were confirmed at autopsy. In the remaining in-

ΔPV, Mean ductal peak systolic flow velocity modulation.

*There was no administration of glucose to the mother.

†No fetal breathing movements could be observed during that measurement.

‡There were no ductal peak flow velocity modulations observed, which is logical since in these cases no fetal breathing movements could be documented.

fant the diagnosis of pulmonary hypoplasia was based on the aforementioned clinical criteria. This infant was treated with 2 months of high-pressure artificial ventilation and now suffers from bronchopulmonary dysplasia and severe brain damage caused by prolonged hypoxia after bilateral pneumothorax. The longitudinal ductal blood flow velocity modulation data (Fig. 3) revealed that two of three fetuses in which pulmonary hypoplasia eventually developed demonstrated a downward trend in ductal blood flow velocity modulation, resulting in values below the 1st percentile of the reference curve.

Comment

Our data demonstrate that during normal pregnancy blood flow velocity waveforms obtained from the fetal ductus arteriosus are modulated by fetal breathing movements. During the inspiration phase of the fetal breathing cycle there is a momentary reduction of ductal systolic peak flow velocity. Because of limitations in the lateral resolution of current ultrasonographic equipment, no accurate measurements of ductal diameter could be obtained. Because dilatation of the fetal ductus arteriosus beyond its resting dimension has not been observed, and agents have not been identified that are capable of such dilatation, it seems unlikely that the reduction in ductal peak systolic flow velocity during fetal breathing activity is caused by increasing ductal diameter.[21] For this reason it is also unlikely that the blood flow velocity changes are caused directly by pressure changes in the fetal chest and abdomen during fetal breathing activity. The observed reduction in ductal peak systolic flow velocity during fetal breathing activity is in agreement with fetal lamb experiments in which it was established that total pulmonary vascular resistance decreased during lung expansion.[4] The subsequent increased perfusion of the pulmonary vascular bed was demonstrated by a rise in pulmonary artery flow and decrease in ductal flow, reflecting reduced right to left shunting. Fetal lamb studies have also

shown that there is a rise in pulmonary blood flow and reduction in pulmonary vascular resistance with advancing gestational age caused by an increase in the total number of pulmonary vessels and increased vasomotor activity.[5] In the human fetus this phenomenon begins during the late canalicular phase (±23 through ±26 weeks) and continues during the saccular and alveolar phase of lung development (±26 through ±40 weeks).[8, 22] This may explain the small modulations in ductal peak systolic flow velocity at 25 weeks and subsequent exponential rise during the third trimester of pregnancy.

In the presence of oligohydramnios lung development may be arrested in the canalicular phase,[23] resulting in reduced lung volume and impaired development of the vascular bed, which is associated with a fixed high pulmonary vascular resistance.[6, 22, 24] This may explain the reduced ductal peak systolic flow velocity modulation observed by us in the fetuses with pulmonary hypoplasia. The predictive value of normal ductal peak systolic flow velocity modulation for continuing lung growth was 100%, as was the predictive value of reduced modulation for pulmonary hypoplasia. Various clinical tests have been suggested with regard to the antepartum diagnosis of developing pulmonary hypoplasia. A close association has been reported between a low fetal thoracic circumference or low thoracic circumference/abdominal circumference ratio and poor neonatal lung performance.[25-27] Both parameters are useful but late indicators of pulmonary hypoplasia. If it is assumed that breathing-related ductal peak systolic flow velocity modulation and pulmonary vascular resistance are inversely related, then the longitudinal data in our study suggest that serial recording of ductal peak systolic flow velocity modulation during breathing activity may be helpful in assessing

the progression of abnormal lung development. Such assessment would allow a more optimal obstetric management in cases of prolonged severe oligohydramnios as a result of ruptured membranes at a stage of pregnancy when extrauterine survival can be expected. A larger longitudinal study is needed to substantiate this premise. The secondary rise in breathing-related ductal peak systolic flow velocity modulation in one case (Fig. 3) may be the result of the administration of 100 mg of indomethacin to the mother shortly before the Doppler flow velocity recording. It has recently been demonstrated that use of the prostaglandin synthetase inhibitor indomethacin may lead to ductal constriction as determined by a significant rise in ductal peak systolic and end-diastolic velocities. In our case mean peak systolic velocity rose from 1.10 to 1.60 m/sec. The subsequent increase in breathing-related ductal peak systolic flow velocity modulation was determined by a more pronounced peak systolic rise during expiration compared with inspiration. Because the constrictive effect of indomethacin may be observed as long as 12 hours after drug administration, studies of ductal flow modulation should be conducted beyond this period.[7, 28] In our study administration of fenoterol was not considered to affect ductal peak systolic flow velocity because the fetal heart rate was within the physiologic range, during which no fetal heart rate dependency of ductal peak systolic flow velocity had been documented.[29] Fetal breathing activity itself has been reported to be helpful in assessment of fetal lung development in cases of prolonged severe oligohydramnios. Fetal breathing movements are important for facilitating lung growth. It has been shown that upper cervical cord injury in rabbit fetuses at 28 to 29 days' gestation results in a reduction in lung weight and total deoxyribonucleic acid content, and injury before 24 days results in retarded maturation. These effects were explained by cessation of fetal breathing activity.[30] Although Blott et al.[2] suggested that the absence of fetal breathing movement is highly predictive for pulmonary hypoplasia, this finding was challenged by Moessinger et al.[3] who stated that observation of fetal breathing activity is not helpful in identifying patients with oligohydramnios at risk of pulmonary hypoplasia. Results of our study support the latter statement. We were unable to observe fetal breathing activity on three occasions in one patient (Table IA) despite maternal intravenous glucose loading; neonatal lung performance was normal. Conversely, fetal breathing movements were established in five fetuses with pulmonary hypoplasia after birth (Table IB).

We conclude that fetal ductal peak systolic flow velocity is modulated by fetal breathing activity in normal late second- and third-trimester pregnancies. This ductal flow modulation exhibits an exponentional increase with advancing gestational age, suggesting the developing pulmonary vascular bed. In cases of prolonged severe oligohydramnios caused by ruptured membranes, normal ductal flow modulation is associated with normal neonatal lung performance, whereas pulmonary hypoplasia was established in cases of reduced ductal flow modulation.

We thank Dr. P. G. H. Mulder (Department of Biostatistics) for statistical advice.

Prenatal diagnosis of a chest wall mass with ultrasonography and Doppler velocimetry

A case report

Leon G. Smith, Jr., MD,[a] Robert J. Carpenter, Jr., MD,[a, b] Whitney Gonsoulin, MD,[a] Giancarlo Mari, MD,[a] Alexander A. Reiter, MD,[a] Frank Greenberg, MD,[a, b] and Carolyn Powell, RN, BSN[a, b]

Houston, Texas

An isolated mass protruding from the chest wall of the fetus was visualized by ultrasonography. Doppler velocimetry over the mass revealed low-resistance blood flow through cystic areas, implicating a highly vascular lesion. An operative delivery was performed to avoid possible rupture of the mass. (Am J Obstet Gynecol 1990;163:567-9.)

Key words: Hemangioma, Doppler velocimetry, prenatal diagnosis

Internal chest tumors have been diagnosed prenatally in numerous cases. However, an external chest wall mass has not been visualized in utero by ultrasonography to our knowledge. An understanding of external tumors located in other anatomic regions of the fetus and application of Doppler velocimetry were helpful in the management of this case.

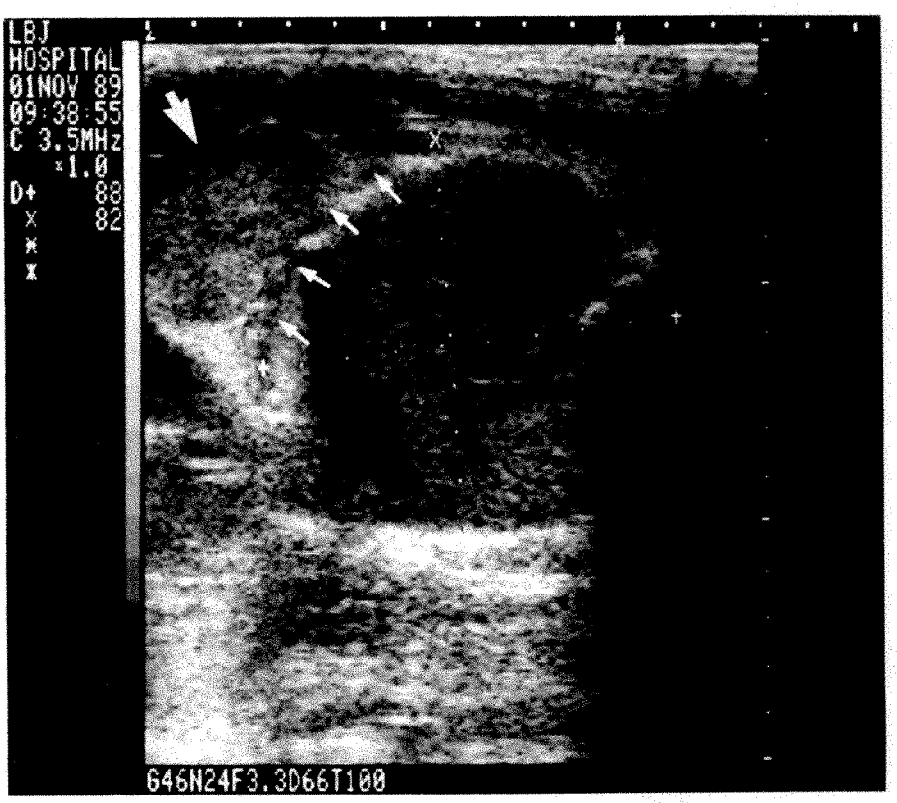

Fig. 1. Ultrasonography of chest circumference. *Small arrows* show outline of chest wall. *Large arrow* demonstrates mass.

Fig. 2. Cavernous hemangioma on infant's chest wall.

Case report

A 17-year-old black primigravid patient was referred to our tertiary care center for an abnormal screening ultrasonogram. Her prenatal course had been unremarkable, including a normal maternal serum α-fetoprotein at 16 weeks' gestation. Her medical history was not significant for any diseases including dermatologic or vascular disorders. The patient denied any use of medications or exposure to drugs during the pregnancy. Her family history disclosed no neural tube defects, mental retardation, or birth defects. The father of the fetus had a history of a right chest wall mass seen at birth and removed at age 6. The pathologic diagnosis was mature teratoma.

Sequential ultrasonography with General Electric model 3000 equipment showed a normal-appearing male fetus except for a discrete right-sided anterior chest wall mass, that did not involve the axilla or neck. Free movement of the upper extremities was noted. The contents within the chest appeared normal, including a four-chamber heart. The mass projected from the external chest and did not appear to penetrate the ribs. It measured 3.4 × 3.1 cm and was echodense with three small (0.3 cm) hypoechoic structures within the tumor. We performed continuous Doppler velocimetry over the mass with a 3.5 MHz transducer. A flow wave pattern with a systolic/diastolic ratio of 1.5 was noted, consistent with blood flow through low resistance channels.[1] Serial ultrasonography with a General Electric model 3200 showed little growth of the mass over the next eight weeks. Fig. 1 shows the mass on real-time ultrasonography.

At 35 weeks' gestation the patient came to the labor and delivery suite with a chief complaint of leakage of fluid per vagina for 6 hours and contractions every 3 minutes. Vaginal examination showed the cervix to be 4 cm dilated and completely effaced with a cephalic presentation. A male infant weighing 2680 gm with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively, was delivered by low transverse cesarean section. A purple, spongy mass was noted on the right anterior chest wall that displaced the areola laterally (Fig. 2). The mass then measured 4.3 × 4.2 cm. No bruits were heard or pulsations felt within the mass. The infant's platelet count was 175,000/cm^3. On the fifth day of life, the infant had the mass resected without difficulty. The histologic diagnosis was cavernous hemangioma. The infant was discharged on the second postoperative day.

At 6 months of age the infant was healthy and doing well.

Comment

The appearance of a solid and cystic mass by ultrasonography elsewhere on the outer surface of the fetus led to a differential diagnosis including teratoma, hemangioma, and mesenchymal sarcoma. With the use of Doppler velocimetry, we demonstrated that the mass had a low-resistance blood flow. Similar results were obtained in a case of a craniofacial hemangioma.[1] We speculate that low vascular resistance as evaluated by Doppler ultrasonography could differentiate vascular lesions such as hemangiomas from neoplasias such as teratomas. However, further Doppler studies of fetal tumors are necessary to substantiate the potential of this diagnostic modality.

The size of the mass did not suggest that soft tissue dystocia was likely. However, a cesarean section was performed because the risk of trauma to a very vascular mass lesion existed. Hemangiomas in the newborn have been noted to have a microangiopathic anemia and thrombocytopenia caused by trauma of the blood elements as flow occurs through the vascular lesion.[2] Therefore abdominal delivery may be appropriate in the management of rare external masses of the fetus.

Relationship of fetal biophysical profile and blood gas values at cordocentesis in severely growth-retarded fetuses

Lucie S. M. Ribbert, MD,[a] Rosalinde J. M. Snijders, MSc,[b] K. H. Nicolaides, MD,[b] and G. H. A. Visser, MD[a]

London, England, and Groningen, The Netherlands

In 14 severely growth-retarded fetuses the biophysical profile score was analyzed in relation to blood Po_2, pH, oxygen saturation, and oxygen content in samples obtained by cordocentesis. The data suggest that the biophysical profile score can predict the degree of fetal acidemia. (Am J Obstet Gynecol 1990;163:569-71.)

Key words: Biophysical profile, cordocentesis, fetal blood gases, intrauterine growth retardation

The biophysical profile is widely used for the assessment of fetal well-being. All previous studies with the biophysical profile have related the results of the test with outcome of pregnancy or with cord blood gas levels at delivery.[1, 2] This study examines the relationship between the biophysical profile and fetal blood gas levels in samples obtained by cordocentesis.

Patients and methods

In 14 severely growth-retarded fetuses that were referred to our unit for further assessment at 25 to 39 weeks' gestation, the biophysical profile was studied immediately before umbilical venous blood sampling. The methods and definitions for fetal tone, fetal gross body movements, fetal breathing movements, amniotic fluid volume, and fetal heart rate reactivity were those described by Manning.[1] Cordocentesis was performed without maternal sedation or fetal paralysis. All fetuses were anatomically and chromosomally normal. The fetal blood gas and hemoglobin levels (grams per deciliter) were measured by Radiometer ABL 330 (Copen-

hagen, Denmark) and Coulter S-plus counter (Coulter Electronics, Luton, England), respectively. The oxygen saturation and oxygen content were calculated. The individual values of the growth-retarded fetuses were subtracted from the appropriate mean for gestation of our reference ranges and expressed as Δ values in SDs [normal ranges: $Po_2 = 62.3 - 0.81 \times$ weeks (mm Hg), SD = 7.51, $n = 268$; $Pco_2 = 28.1 + 0.25 \times$ weeks (mm Hg), SD = 3.23, $n = 268$; pH = $7.47 - 0.002 \times$ weeks, SD = 0.03, $n = 268$; oxygen saturation = $1.013 - 0.007 \times$ weeks (%), SD = 0.06, $n = 268$; hemoglobin = $7.6 + 0.18 \times$ weeks (gm/L),

SD = 1.2, n = 555; oxygen content = 5.36 + 0.03 × weeks (mmol/L), SD = 0.73, n = 194].

Results

Fetal blood sampling data, the biophysical profile score, and pregnancy outcome are given in Table I. The biophysical profile score was significantly correlated to Δ pH (n = 14, r = 0.840, $p < 0.001$; Fig. 1) but not to Δ Po_2 (r = 0.25), Δ Pco_2 (r = −0.25), Δ oxygen saturation (r = 0.25), Δ hemoglobin (r = 0.34), or Δ oxygen content (r = 0.48). Although the indices of oxygenation (Po_2, oxygen saturation, oxygen content) were lower in the group of fetuses with nonreactive fetal heart rate or absent fetal breathing movement than in the group with reactive fetal heart rate and the presence of fetal breathing movement, the differences were not statistically significant.

Comment

This preliminary study in a group of highly compromised growth-retarded fetuses suggests that the biophysical profile score can predict the degree of fetal acidemia and confirms the findings of Vintzileos et al.[2] that fetal heart rate reactivity and fetal breathing movements are the first, whereas fetal gross body movement and tone are the last biophysical activities to be compromised during acidemia. If the aim of antenatal testing is to diagnose fetal acidemia, more useful information is obtained from the sequential examination of the individual components of the biophysical profile score than the total score. A reactive fetal heart rate was always associated with a pH above the 2.5th percentile. A nonreactive fetal heart rate can be investigated further by sonography for the diagnosis of oligohydramnios, which was always associated fetal acidemia. However, absence of oligohydramnios, certainly for fetuses of <32 weeks' gestation, does not exclude acidemia. Subsequent sonographic examination for fetal tone and activity will help distinguish between acidemic and nonacidemic fetuses in the majority of cases; indeed, absence of tone and fetal gross body movements may identify a subgroup of severely acidemic fetuses. Further improvement of the biophysical profile score may be obtained by quantification of the incidence of movements and use of a fetal heart rate classification that takes into account the gestational effect on reactivity.

Successful treatment of postpartum shock caused by amniotic fluid embolism with cardiopulmonary bypass and pulmonary artery thromboembolectomy

Rick A. Esposito, MD,[a] Eugene A. Grossi, MD,[a] Gene Coppa, MD,[a] Gary Giangola, MD,[a] Donald P. Ferri, MD,[b] Elaine M. Angelides, MD,[a] and Peter Andriakos, MD[a]

New York, New York, and Monmouth, New Jersey

We report the successful treatment of a moribund patient as a result of amniotic fluid embolism with cardiopulmonary bypass and open pulmonary artery thromboembolectomy. Review of the literature indicates that this is the first reported case of treatment of amniotic fluid embolism with cardiopulmonary bypass and pulmonary thromboembolectomy. (Am J Obstet Gynecol 1990;163:572-4.)

Key words: Amniotic fluid embolism, postpartum shock, disseminated intravascular coagulation

Amniotic fluid embolism is a highly lethal disorder that complicates an estimated 1 in 30,000 pregnancies. Despite its rarity it remains the most common cause of death in labor, during pregnancy, and in the immediate postpartum period. The breakdown of the maternal-fetal barrier with the release of fetal particulate matter into the maternal circulation is responsible for the clinical manifestations of this disorder, which include cardiovascular collapse, pulmonary arterial thrombosis, and severe coagulopathy. Because there has been no specific therapy for this disorder, treatment has traditionally been supportive and involves the maintenance of blood volume, pharmacologic support of the circulation, administration of oxygen, and attempted reversal of the coagulopathy with blood components. Despite these efforts the outcome has remained dismal with an overall expected mortality of 86%.[1] Theoretically, an attempt at surgical removal of the fetal products of gestation and thrombus from the maternal pulmonary circulation should be advantageous in restoration of normal physiologic characteristics. This approach was first suggested by Altcheck and Litwak[2] in 1966, but to our knowledge has not been used clinically until this report.

Case report

A 29-year-old woman, gravida 4, para 4, was air evacuated to Bellevue Hospital on Nov. 12, 1988, for the treatment of postpartum shock. Earlier that day the patient had undergone an uncomplicated cesarean section of a 40-week gestation with the delivery of a normal female infant. One hour postpartum the patient sustained a sudden cardiopulmonary arrest. She was resuscitated with closed cardiac massage and assisted ventilation. Marginal blood pressure was maintained with a large dose of inotropic drugs. The diagnosis of pulmonary embolism was suspected as a result of significant arterial desaturation. A pulmonary perfusion scan demonstrated massive embolism to the left lung (Fig. 1, *A*).

The patient was transferred to Bellevue Hospital for possible surgical thrombectomy. On arrival the systolic blood pressure was 80 mm Hg with the patient receiving 30 μg/min/kg dopamine infusion. Arterial blood gas determination demonstrated severe desaturation (Po_2 of 80 torr with complete assisted ventilation; Fio_2, 1.00). In addition, there was external evidence of severe ongoing coagulopathy with bleeding from all intravenous puncture sites, the vagina, and the abdominal incision. Because the patient was too unstable for further workup, she was taken directly to the operating room.

The heart was exposed through a median sternotomy incision. The most striking finding was a distended right ventricle that was contracting poorly. After full heparinization, cardiopulmonary bypass was instituted at a flow rate of 2 L/min/m² at a temperature of 32° C. Cardioplegic arrest was obtained with cold blood potassium cardioplegia; continuous topical hypothermia was maintained with cooled saline solution.

The pulmonary artery was then opened axially starting at the main pulmonary artery and directed onto

Fig. 1. Pulmonary perfusion scans: preoperative **(a)**, 2 weeks after operation **(b)**, and 3 months after operation **(c)**.

the left pulmonary artery. A large amount of friable thrombus was removed, most of which formed a cast of the pulmonary arterial tree. Subsequent microscopic examination of this material demonstrated a high concentration of fetal squamous cells, confirming the diagnosis of amniotic fluid embolism. The incision was then closed with a running 5-0 Prolene suture (Ethicon, Inc., Somerville, N.J.).

The patient was then weaned from cardiopulmonary bypass. Arterial blood gas levels demonstrated a significant improvement in the oxygenation (Po_2 of 375 torr, Fio_2 of 1.00). The right heart was also significantly less distended and now contracted vigorously on a much lower dose of inotropic agents (dobutamine, 7 μg/kg/min).

After protamine reversal of heparinization it was apparent that a severe coagulopathy was present that necessitated multiple transfusions of blood components. Subsequent analysis of blood drawn preoperatively revealed evidence of severe disseminated intravascular coagulation (Table I). While hemostasis was being obtained in the mediastinum, the abdominal girth was noted to be enlarging. Abdominal paracentesis revealed bleeding, and an exploratory laparotomy was done through a midline incision. Several small bleeding points were oversewn along the hysterotomy incision, resulting in control of the hemorrhage. Both incisions were then closed. Repetition of the coagulation profile 4 hours after operation demonstrated complete resolution of the disseminated intravascular coagulation (Table I).

On the second postoperative day a Greenfield filter was placed in the inferior vena cava as prophylaxis against any further emboli. Repeat lung scan done 3 weeks after operation revealed a restoration of perfusion to the left upper lobe and minimal perfusion to the left lower lobe (Fig. 1, *B*). Oral anticoagulation was begun and continued for 3 months; repeat lung perfusion scan done then demonstrated complete return of blood flow to the left lung (Fig. 1, *C*). The patient has returned to a fully normal and productive life without any residual disability.

*Four hours after operation.

Comment

Traditionally the diagnosis of amniotic fluid embolism has been made by postmortem examination of the pulmonary artery contents. Demonstration of fetal cells in this specimen is considered to be pathognomonic of this disorder. Antemortem diagnosis has been confined to the finding of fetal squamous cells in the maternal circulation retrieved either through a central venous or pulmonary artery catheter; however, this method is imprecise because of a high false-positive yield.[3] Therefore extraction of the pulmonary artery thrombus during pulmonary thrombectomy and subsequent pathologic examination represents the most accurate means of establishing the diagnosis during life. Of greater importance is the ability to immediately relieve the pulmonary arterial obstruction by removal of the thromboembolus. Although restoration of the blood flow to

the lung was incomplete in our patient as demonstrated by early postoperative perfusion scan, it was not clinically significant because there was prompt reversal of the intrapulmonary shunting and a greatly diminished need for inotropic support. In this case, the limited perfusion of the left lower lobe most likely represents thrombosis of small pulmonary arterioles that were not accessible to thrombectomy. The outcome may have been affected more favorably had thrombectomy been performed earlier. Nonetheless, by 3 months after operation the pulmonary blood flow had returned to a completely normal level.

Severe life-threatening hemorrhage is another characteristic of amniotic embolism that occurs in 40% of such patients.[1] The prominent feature appears to be disseminated intravascular fibrin deposition in response to the procoagulant effect of amniotic fluid. The coagulation profiles performed in our patient illustrate this point. Preoperatively there was evidence of disseminated intravascular coagulation, which was completely reversed by 4 hours after operation. Although this dramatic improvement coincides with the administration of blood components, it is certain that the removal of the procoagulant stimulus by thrombectomy was beneficial in reversing the coagulopathy. Furthermore, treatment of the coagulopathy by simple replacement therapy without removal of the thrombogenic stimulus may aggravate the pulmonary vascular obstruction by causing continued thrombogenesis and resulting in progressive arterial desaturation and right heart failure.

In conclusion, on the basis of this case report, emergent pulmonary thrombectomy for postpartum shock caused by amniotic fluid embolism is helpful in establishing a diagnosis in vivo, restoring pulmonary blood flow and normal physiologic function as arterial oxygenation, normal right heart function, and hemodynamic stability, and reversing a life-threatening coagulopathy. Further application of this technique is indicated to fully assess its merit.

Antiphospholipid antibodies and recurrent pregnancy loss: Correlation between the activated partial thromboplastin time and antibodies against phosphatidylserine and cardiolipin

Neal S. Rote, PhD,[a, b, c] Dorene Dostal-Johnson, MS,[a, b] and D. Ware Branch, MD[d]
Scarborough and Portland, Maine, and Salt Lake City, Utah

Concordance was determined among the presence of the lupus anticoagulant measured by prolongation of the activated partial thromboplastin time and IgG and IgM antibodies against phosphatidylserine and cardiolipin in 47 patients selected for study because of histories of recurrent spontaneous pregnancy loss and a positive test for at least one antiphospholipid antibody. Forty-five of 47 patients (96%) had a prolonged activated partial thromboplastin time, ranging from 46 to 150 seconds. Elevated levels of IgG antiphosphatidylserine antibodies and IgM antiphosphatidylserine antibodies were present in 41 (87%) and in 19 (40%) of samples, respectively. Antibodies against cardiolipin were less commonly observed; IgG anticardiolipin antibodies in only 32 (68%) of 47 samples and IgM anticardiolipin antibodies in 15 (36%) of 42 samples. Neither the level of IgG antiphosphatidylserine antibodies nor the level of IgG anticardiolipin antibodies correlated well with the degree of prolongation of coagulation in the activated partial thromboplastin time ($R = 0.312$, $p = 0.032$ for IgG antiphosphatidylserine antibodies versus activated partial thromboplastin time; $R = 0.251$, $p = 0.088$ for IgG anticardiolipin antibodies versus activated partial thromboplastin time). Concordance with the activated partial thromboplastin time, however, was observed in 41 (87%) samples for IgG antiphosphatidylserine antibodies and in only 32 (68%) samples for IgG anticardiolipin antibodies. Our conclusion is that the antiphosphatidylserine assay correlates best, although not totally, with the presence of lupus anticoagulant and that the antiphosphatidylserine assay is more sensitive than testing for anticardiolipin. (Am J Obstet Gynecol 1990;163:575-84.)

Key words: Recurrent pregnancy loss, autoimmune disease, lupus anticoagulant, antiphospholipid antibodies, anticardiolipin antibody, antiphosphatidylserine antibody, activated partial thromboplastin time

The production of autoantibodies directed against membrane phospholipids has been strongly associated with a variety of medical disorders including thromboembolic disease, recurrent pregnancy loss, intrauterine growth retardation, severe pregnancy-induced hypertension, and thrombocytopenia.[1-5] Patients with this autoimmune disorder may produce an antibody, or a family of antibodies, that can be measured either by prolongation of in vitro phospholipid–dependent coagulation tests, by an enzyme-linked immunosorbent assay (ELISA) using crude extracts of human brain as antigen,[6, 7] or by ELISAs or radioimmunoassays (RIAs) using acidic phospholipids as antigens.[8-10] The lupus anticoagulant was the first antiphospholipid antibody described and remains the standard against which all other assays are compared.[11, 12] The recommended approach to convincingly determine the presence of the lupus anticoagulant should include a screening test for prolonged coagulation and the identification of the presence of an inhibitor.[13] Although patients with factor VIII inhibitors can usually be differentiated clinically by a tendency for prolonged bleeding rather than thrombosis, a confirmatory test addressing the antiphospholipid nature of the inhibitor may be incorporated into the testing. Lupus anticoagulant is detected in most laboratories by the prolongation of the activated partial thromboplastin time (APTT). The APTT, however, has been labeled less sensitive than other screening tests primarily for two reasons: the test is prone to the effects of altered levels of normal coagulation factors, which may be elevated during pregnancy, and the content of procoagulatory phospholipids, especially phosphatidylserine, may vary considerably among com-

mercially available preparations of partial thromboplastin.[13] In addition, the APTT is cumbersome and the specificity and class of the antibody that prolongs coagulation cannot be readily identified.

Recently many laboratories have proposed that adequate diagnosis of this autoimmune disorder can be made by means of an assay for the anticoagulant activity plus an ELISA for antibody against cardiolipin.[14] In one of the original studies a good correlation was observed between the amount of IgG antibody against cardiolipin and the degree of prolongation of coagulation in the kaolin clotting assay.[14] In most studies, however, the prolongation of coagulation does not correlate well with the degree of reactivity in any ELISA, including assays in which partial thromboplastin is used.[6, 7, 10, 12] We and others have previously suggested that measurement of antibodies against another phospholipid, phosphatidylserine, may be as good as, if not superior to, the use of assays for anticardiolipin.[10, 12]

To investigate the relative efficacy of immunoassays for antiphosphatidylserine and anticardiolipin we used quantitative ELISA techniques and investigated the relationship of antiphosphatidylserine antibodies and anticardiolipin antibodies to the incidence of lupus anticoagulant in 47 women with recurrent pregnancy loss.

Patients and methods

Patients. We studied serum samples obtained from 47 women who were selected from patients referred to the Obstetric Clinic at the University of Utah Medical Center for evaluation of recurrent pregnancy loss. All patients had at least two consecutive pregnancy losses, and only seven had a diagnosis of systemic lupus erythematosus. The patients were selected on the basis of a positive test for at least one antiphospholipid antibody: either the presence of lupus anticoagulant or an IgG or IgM antibody against phosphatidylserine or cardiolipin. Serum from five patients was not available for testing for IgM antibody against cardiolipin, although in each case the patient had positive results for the lupus anticoagulant and IgG antibody against cardiolipin.

Plasma for the coagulation studies was collected in sodium citrate tubes (0.015 mol/L buffered citrate, Becton-Dickinson Vacutainer Systems, Rutherford, N.J.) by venipuncture and the coagulation assay was performed within 2 hours. Serum was obtained by venipuncture in Vacutainer blood collecting tubes without anticoagulants (Becton-Dickinson) at the same time as the coagulation sample was drawn. The blood was allowed to clot at room temperature and was then centrifuged at 175 *g* for 10 minutes. The serum was aspirated with a plastic pipette and stored in 1 ml aliquots in polyethylene tubes at −70 C° until use.

Laboratory methods. The lupus anticoagulant was present when the patient's plasma demonstrated prolongation of the activated partial thromboplastin time without correction by the addition of normal plasma at a ratio of 1:1. The APTT was performed in the Coagulation Laboratory at the University of Utah with a partial thromboplastin prepared from human brain as described previously.[10] Preparations of partial thromboplastin were titrated against a battery of normal plasma so that a coagulation time of longer than 45 seconds was considered abnormally prolonged.

Antibodies against cardiolipin and phosphatidylserine were measured by an ELISA procedure that has been previously described.[5, 15, 16] Immulon I, 96-well microtiter plates (Dynatech Labs, Alexandria, Va.) were prepared by diluting the individual phospholipids (Sigma Chemicals, St. Louis) in absolute ethanol to a final concentration of 45 μg/ml and adding 30 μl to each well. The solvent was allowed to evaporate overnight at room temperature. Nonspecific binding was blocked by addition of 130 μl of a 10% solution of fetal bovine serum (Gibco, Buffalo, N.Y.) in phosphate-buffered saline solution (pH 7.2 to 7.4) to each well and incubating at 20° to 25° C for 1 hour. The plates were washed three times with fetal bovine serum–phosphate-buffered saline solution with 1- to 2-minute incubation periods during the washes. After incubation 100 μl of a 1:32 dilution of each serum was added in duplicate and incubated for 1 hour at 20° to 25° C. After three washings 100 μl of goat anti-human IgG (1:500 dilution) or goat anti-human IgM (1:1000 dilution) (Fc fragment–specific, Cooper Biomedical, Malvern, Pa.) was added and incubated at 20° to 25° C for 1 hour. After three washings 100 μl of a 1:800 dilution of peroxidase conjugated rabbit anti-goat IgG (Fc fragment–specific, Cooper Biomedical) was added to each well and the plates incubated for 1 hour. The plates were washed three times and color development was induced by adding 100 μl of an indicator (one volume of 0.05% hydrogen peroxide plus nine volumes of 0.08% 5-amino salicylic acid, pH 6.0) and incubated for 15 minutes. Color development was stopped with 30 μl of 1N sodium hydroxide and the optical density was read at 450 nm on a Microplate Autoreader (Bio-Tek Instruments, Inc, Winooski, Vt.).

All spectrophotometric readings were adjusted by subtracting the readings observed on nonspecific-binding plates (plates that did not receive phospholipid although they were processed in an identical fashion) and converting the resultant values to standard deviations above the mean (SD) by use of the current means and standard deviations of the optical densities from an ongoing accumulation in our laboratory of more than 1000 normal control individuals. Each plate contained laboratory positive control sera that were validated against externally provided reference sera. The

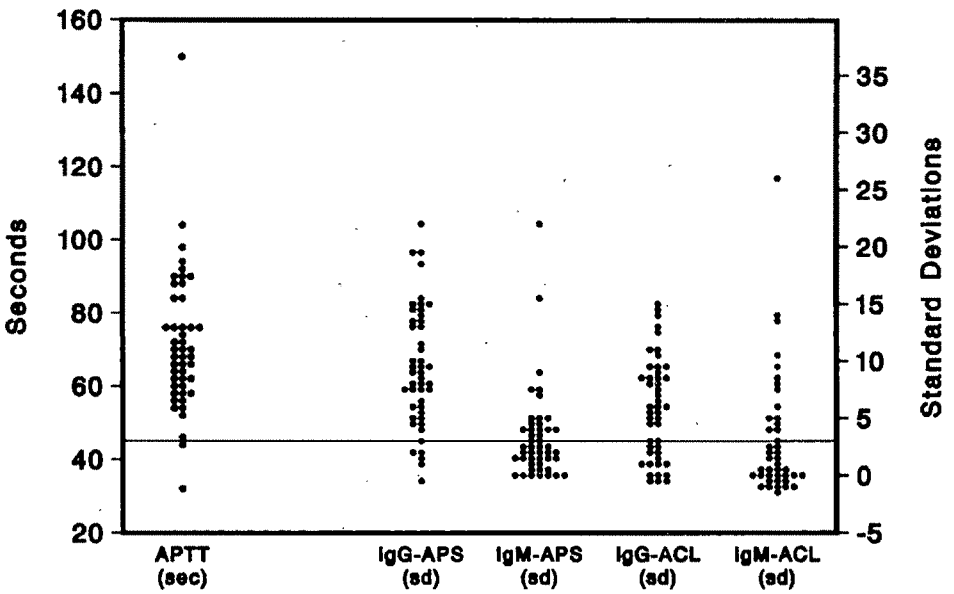

Fig. 1. Distribution of the APTT, IgG and IgM antibodies against phosphatidylserine *(IgG-APS* and *IgM-APS)*, and IgG antibodies against cardiolipin *(IgG-ACL)* in 47 patients with a history of recurrent pregnancy loss. Forty-two of these patients were also tested for IgM antibodies against cardiolipin *(IgM-ACL)*. The APTT is expressed in seconds and the other assays are expressed in standard deviations above the mean of the normal controls. The horizontal line denotes the upper limit of normal in all assays (45 seconds or 3 SDs).

Table I. APTT and levels of IgG and IgM antibodies against phosphatidylserine and cardiolipin in women with recurrent pregnancy loss

*Antiphospholipid antibody assay**	*Range*	*Mean*	*SD*	*Median*	*Positive†* *(%)*
APTT (sec)	32-150	71	19	67	96
IgG antiphosphatidylserine (SD)	−0.9-22.1	9.5	5.3	8.8	87
IgM antiphosphatidylserine (SD)	−0.5-21.8	3.3	4.0	2.4	40
IgG anticardiolipin (SD)	−1.0-15.2	5.9	4.5	5.8	68
IgM anticardiolipin (SD)	−1.8-26.0	3.1	5.5	1.2	36

*47 samples were assayed, except for IgM anticardiolipin, in which only 42 were available.

†For the APTT positive is defined as >45 seconds, and for the ELISAs positive is defined as >3 SD above the mean of the normal controls.

means and standard deviations used for each assay are as follows: IgG antiphosphatidylserine, 0.037 ± 0.022; IgM antiphosphatidylserine, 0.032 ± 0.027; IgG anticardiolipin, 0.070 ± 0.033; and IgM anticardiolipin, 0.046 ± 0.019.

The means between each group were compared with the Wilcoxon signed-rank test for paired samples. Correlations between individual tests were calculated with the Spearman rank method. Proportions from the paired samples were analyzed with the exact binomial distribution on the untied samples.

Results

All available patient samples were evaluated for antiphospholipid antibodies by the APTT and ELISAs for IgG and IgM antibodies against phosphatidylserine, and cardiolipin (Fig. 1 and Table I). The APTT values ranged from 32 seconds to 150 seconds; a coagulation time of longer than 45 seconds was considered abnormal. Plasma from 45 of the 47 patients (96%) had a prolonged APTT, none of which corrected on the addition of normal plasma. Of antibodies tested by ELISA, IgG antiphosphatidylserine antibodies were the most prevalent; 87% of the samples were >3 SD above the mean of our normal controls and the median level was 8.8 SDs. IgM antiphosphatidylserine antibodies were less prevalent; 40% of the samples were elevated and the median level was 2.4 SDs. IgG anticardiolipin antibodies were also present in most patients; 68% of the samples were positive with a median of 5.8 SDs.

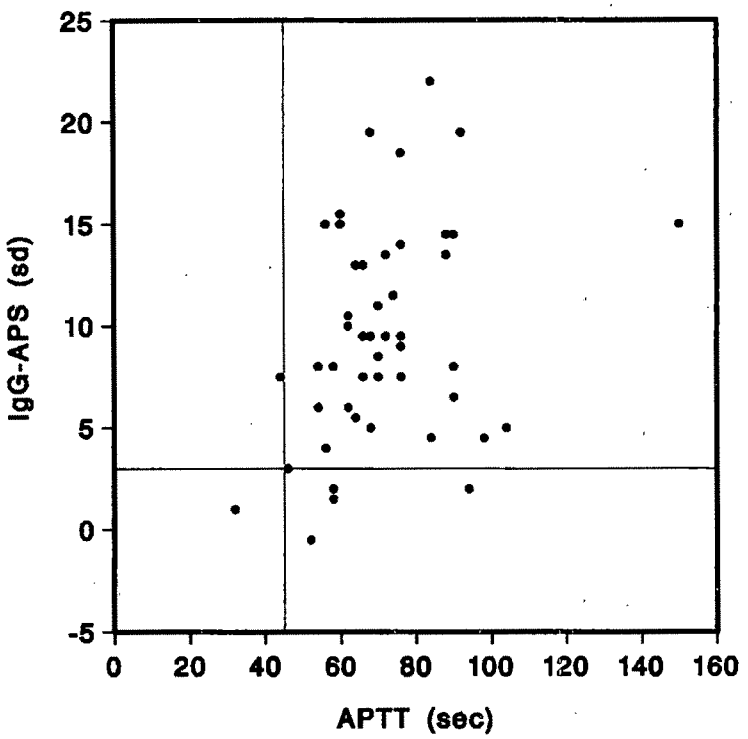

Fig. 2. Scatterplot shows the levels of IgG antibodies against phosphatidylserine (*IgG-APS* on the *Y* axis, expressed in standard deviations above the mean of normal controls) and the APTT (on the *X* axis, expressed in seconds) in 47 patients with recurrent pregnancy loss. Regression line: $Y = 0.087X + 3.299$; $R = 0.312$; $p = 0.03$.

The assay for IgM anticardiolipin antibodies had the lowest frequency of positive results (36%) with a median of 1.2 SDs. All paired ELISA results were significantly different ($p < 0.05$) from each other with the exception of IgM antiphosphatidylserine antibodies versus IgM anticardiolipin antibodies.

The amount of both IgG antiphosphatidylserine antibodies and IgG anticardiolipin antibodies correlated weakly with the degree of prolongation of coagulation in the APTT (Figs. 2 and 3). When compared with the prolongation of the APTT, IgG antiphosphatidylserine antibodies had a correlation coefficient of 0.312 ($p = 0.032$) and the IgG anticardiolipin antibodies had a correlation coefficient of 0.251 ($p = 0.088$).

Concordance between the APTT and each of the ELISAs for antibodies against phosphatidylserine and cardiolipin can also be seen in Figs. 2 and 3. The results of the APTT were accurately predicted by the presence or absence of IgG antiphosphatidylserine antibodies in 41 of 47 (87%) samples (40 samples were positive by both assays and one sample was negative by both). Six samples were not in agreement; five were prolonged in the APTT and negative for IgG antiphosphatidylserine antibodies and one had a normal APTT and elevated IgG antiphosphatidylserine. The assay for IgG anticardiolipin antibodies agreed less well with the APTT, with only 32 (68%) samples in which the APTT and the assay for IgG anticardiolipin antibodies agreed (31 were positive in both assays and one was negative for both). In 15 samples, however, the APTT was not accurately predicted by the assay for IgG anticardiolipin antibodies; 14 of the samples had prolonged clotting times and were negative for IgG anticardiolipin antibodies, whereas one sample that was positive for IgG anticardiolipin antibodies had a normal clotting time. The difference between the concordance of IgG antiphosphatidylserine antibodies and IgG anticardiolipin antibodies with the APTT was significant at $p = 0.04$. When IgG and IgM antibodies were simultaneously evaluated both assays improved in capacity to predict the APTT; combined assays for IgG antiphosphatidylserine antibodies and IgM antiphosphatidylserine antibodies was inaccurate in only four samples, whereas combined assays for IgG anticardiolipin antibodies and IgM anticardiolipin antibodies was inaccurate in 12 samples. The difference between antiphosphatidylserine and anticardiolipin combined IgG and IgM assays was significant at $p = 0.03$. Sensitivity of the combined IgG and IgM assays for antiphosphatidylserine in relationship to prolongation of the APTT was 91%, whereas the sensitivity of the assays for anticardiolipin was 73%.

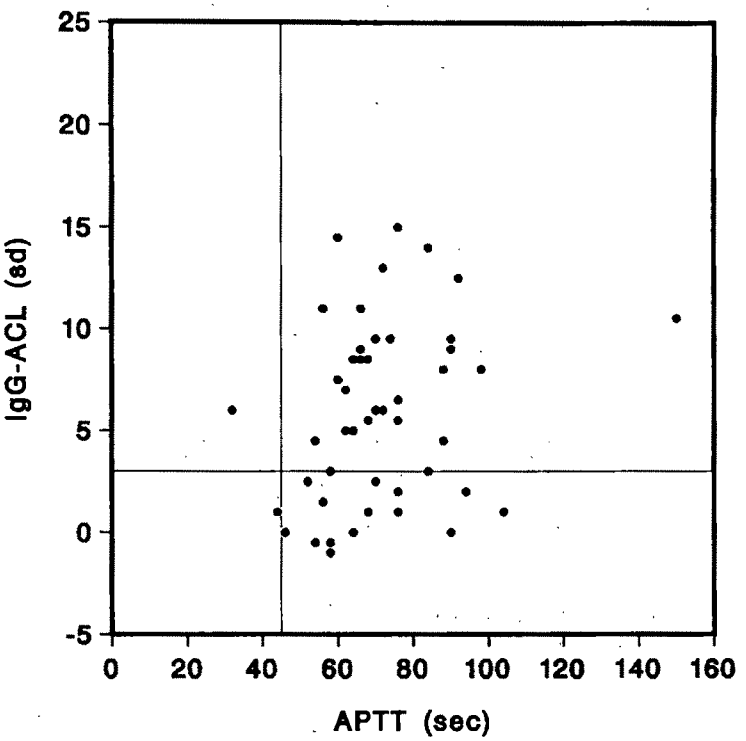

Fig. 3. Scatterplot shows the levels of IgG antibodies against cardiolipin (*IgG-ACL* on the *Y* axis, expressed in standard deviations above the mean of normal controls) and the APTT (on the *X* axis, expressed in seconds) in 47 patients with recurrent pregnancy loss. Regression line: $Y = 0.059X + 1.656$; $R = 0.251$; $p = 0.09$.

The best correlations were observed when antibodies of the same class were compared. The amount of IgG antiphosphatidylserine antibodies correlated well with the amount of IgG anticardiolipin antibodies ($R = 0.665$, $p < 0.001$) (Fig. 4). Several samples, however, contained one specificity without the other; eleven (23%) specimens were negative for IgG anticardiolipin antibodies yet had elevated amounts of IgG antiphosphatidylserine antibodies, although these elevations were never greater than 9 SDs. Only two (4%) samples had IgG anticardiolipin antibodies without elevated IgG antiphosphatidylserine antibodies, and both had relatively low amounts of IgG anticardiolipin antibodies (3.2 and 6.0 SD).

The best comparison was between assays for IgM antiphosphatidylserine antibodies and IgM anticardiolipin antibodies ($R = 0.749$, $p < 0.001$) (data not shown). This may be somewhat misleading because the plurality (23 or 48.9%) of the samples were negative for both antibodies and comparison of the positive samples was not as significant ($R = 0.671$, $p = 0.031$). None of the other correlations were statistically significant (R values between 0.239 and -0.143).

Tables II and III allow simultaneous comparisons of all three assays. Table II compares in a pair-wise fashion the proportion of samples in agreement between IgG antiphosphatidylserine antibodies and APTT with the proportion in agreement between IgG anticardiolipin antibodies and APTT. In 35 patients, both pairs of tests were concordant; i.e., in 30 patients the APTT, assays for IgG antiphosphatidylserine antibodies, and assays for IgG anticardiolipin antibodies all agreed on the presence of antiphospholipid antibody, and in an additional five patients, assays for IgG antiphosphatidylserine antibodies and IgG anticardiolipin antibodies both disagree with the APTT results. In 11 of the 12 remaining patients, the assay for IgG antiphosphatidylserine antibodies agreed with the APTT, whereas the assay for IgG anticardiolipin antibodies did not ($p < 0.003$ by an exact binominal test with the probability of agreement = 0.5). The single sample in which the assay for IgG anticardiolipin antibodies was concordant with the APTT, whereas the assay for IgG antiphosphatidylserine antibodies was not concordant, was from a patient with multiple pregnancy losses, a normal APTT, negative assays for IgG anticardiolipin antibodies and IgM anticardiolipin antibodies, and a positive assay for IgG antiphosphatidylserine antibodies.

Table III compares in a similar fashion the proportion of samples in concordance with the APTT using either IgG or IgM antiphosphatidylserine antibodies and IgG or IgM anticardiolipin antibodies. The anti-

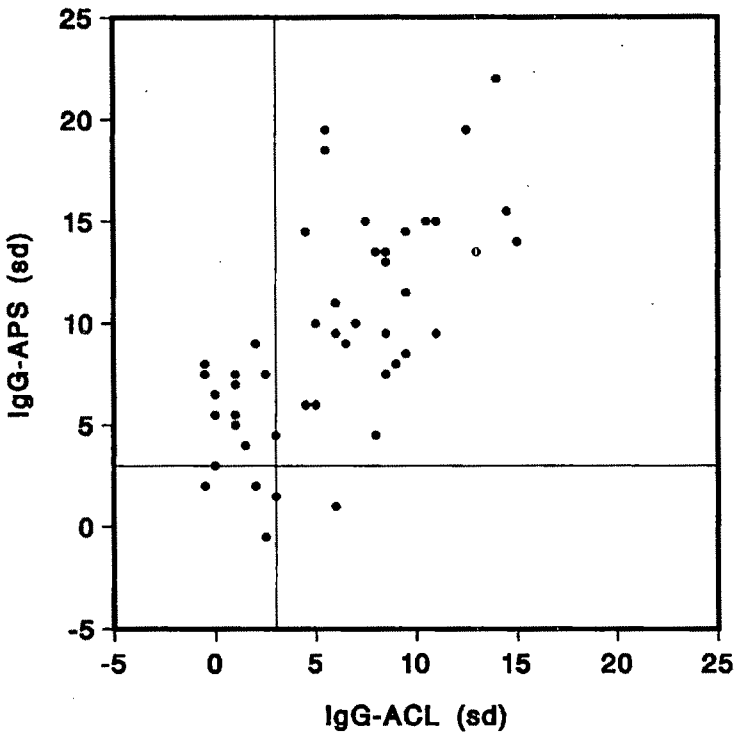

Fig. 4. Scatterplot shows the levels of IgG antibodies against phosphatidylserine (*IgG-APS* on the *Y* axis, expressed in standard deviations above the mean of normal controls) and the levels of IgG antibodies against cardiolipin (*IgG-ACL* on the *X* axis, expressed in standard deviations above the mean of normal controls) in 47 patients with recurrent pregnancy loss. Regression line: $Y = 0.780X + 4.864$; $R = 0.665$; $p < 0.001$.

phosphatidylserine assay is significantly more concordant with the APTT than is the anticardiolipin assay ($p = 0.03$). The incorporation of IgM antiphosphatidylserine antibodies lowers the number of samples that show lack of concordance between antiphosphatidylserine and APTT from six (Table II) to four. Therefore two samples had prolonged APTTs with IgM antiphosphatidylserine antibodies without accompanying IgG antiphosphatidylserine antibodies. Of the remaining four that show lack of concordance, one has a normal APTT with the presence of antiphosphatidylserine and three have prolonged APTTs with normal levels of antiphosphatidylserine. The incorporation of IgM anticardiolipin antibodies decreased the number of samples that show lack of concordance between the anticardiolipin assay and APTT from 16 to 12; therefore four samples had prolonged APTTs and IgM anticardiolipin antibodies, without IgG anticardiolipin antibodies. The number of samples with complete concordance among APTT, anticardiolipin, and antiphosphatidylserine increased from 30 to 32, indicating that two samples with prolonged APTTs were negative for IgG antibodies against either phosphatidylserine or cardiolipin but contained IgM antibodies against both phospholipids. Two additional samples show a lack of concordance between the APTT and the antiphosphatidylserine assays, yet are concordant between the APTT and anticardiolipin assays. These samples therefore were characterized by prolonged APTTs and the presence of IgM anticardiolipin antibodies, without IgG anticardiolipin antibodies, IgG antiphosphatidylserine antibodies, or IgM antiphosphatidylserine antibodies.

Comment

In this study we focused on 47 women who were referred to our clinic with a history of recurrent pregnancy loss. Only seven patients were diagnosed as also having signs of systemic lupus erythematosus. This patient population immediately sets our study apart from most of the published studies on antiphospholipid antibodies, which described patient populations containing larger proportions of patients with systemic lupus erythematosus. However, in our experience the majority of patients referred for pregnancy loss associated with antiphospholipid antibodies do not have systemic lupus erythematosus. The purpose of this study was to compare the diagnostic efficacy of ELISA procedures for antibodies against cardiolipin and phosphatidylserine as an adjunct to assays for anticoagulant activity. These 47 patients were selected, therefore, because of a history of recurrent pregnancy loss and the presence of an antiphospholipid antibody by a positive reaction

in any of the five assays described in this study; the APTT, IgG and IgM antibodies against cardiolipin, and IgG and IgM antibodies against phosphatidylserine. The patients consisted of a mixture of women with primary and secondary abortions with pregnancy losses in both the second and first trimester. There was no significant correlation between reactivity in any of our laboratory tests and any clinical manifestation, including a history of thrombosis or timing of pregnancy loss. Many more patients with recurrent pregnancy loss were tested and had negative results in all five tests.

Previously reported results of patients with systemic lupus erythematosus appear contradictory. Our data agree with Meyer et al.,[17] who observed relatively good correlation coefficients of 0.47 and 0.64 between levels of anticardiolipin antibodies and prolongation of the APTT, and between levels of antiphosphatidylserine antibodies and the APTT, respectively. Other studies, however, have reported in patients with systemic lupus erythematosus that 24% had lupus anticoagulant without anticardiolipin and 42% had elevated levels of anticardiolipin without lupus anticoagulant, and that there was no correlation between APTT values and anticardiolipin levels (correlation coefficient of 0.0057).[18] Results from other groups who studied primarily patients with systemic lupus erythematosus have shown that 55% to 100% of patients with positive lupus anticoagulant results have raised levels of IgG anticardiolipin antibodies and 35% to 86% of patients with positive IgG anticardiolipin antibodies results have lupus anticoagulant, depending on the particular assay used to detect lupus anticoagulant.[19-21] Sensitivity of the anticardiolipin assay for detecting lupus anticoagulant was approximately 77%.[21] One recent study included 100 patients with positive lupus anticoagulant results, of whom only eight had recurrent pregnancy loss.[12] Only 73% of the patients had detectable IgG or IgM antibodies, or both, against one of four phospholipids (cardiolipin, phosphatidylserine, phosphatidic acid, or phosphatidylinositol). Of these, 29% had IgG antibodies alone, 56% had both IgG and IgM antibodies, and 15% had IgM antibodies alone. Distribution of antiphospholipid antibodies was as follows: anticardiolipin, 61%; antiphosphatidylserine, 60%; antiphosphatidic acid, 54%; and antiphosphatidylinositol, 47%. Nine patients had a positive reaction against a single phospholipid (three against cardiolipin, two against phosphatidylserine, four against phosphatidylinositol). These results agree with some of our previous observations that sera from patients with positive lupus anticoagulant results most commonly contained antibodies against phosphatidylserine and cardiolipin, with 40% having IgG antibodies alone and 60% having IgG and IgM antibodies, and that many patients also had antibodies against a large number of other phospholipids: 80% against phosphatidylethanolamine, 80% against phosphatidylglycerol, and 67% against phosphatidylinositol.[10]

The recommended approach to convincingly determine the presence of the lupus anticoagulant should include a screening test for prolonged coagulation and the identification of the presence of an inhibitor.[13] At least four screening tests are currently available and the advantages and disadvantages of each have been recently thoroughly reviewed.[13] We usually recommend the activated partial thromboplastin time to screen for the lupus anticoagulant because clinicians are familiar with it and the test is widely available. The activated partial thromboplastin time, however, has been labeled less sensitive than other screening tests primarily for two reasons: the test is prone to the effects of altered levels of normal coagulation factors, which may be elevated during pregnancy, and the content of procoagulatory phospholipids, especially phosphatidylserine, may vary considerably among commercially available preparations of partial thromboplastin.[13] However, if the activated partial thromboplastin time is used to test patients who are not currently pregnant, which is the

majority of patients being evaluated, the problem of pregnancy-associated elevations in the levels of coagulation factors can be avoided. In addition, the laboratory must be sensitive to variations in batches of partial thromboplastin and titer each preparation to standardize the assay. Personnel of the Coagulation Laboratory at the University of Utah, where the APTT described in this study was performed, prepare and carefully standardize their own partial thromboplastin extracted by chloroform/methanol from human or bovine brain; this process results in a very sensitive, reproducible, and specific reagent. Therefore the incidence of lupus anticoagulant in this report is characteristic only of that particular laboratory and would, most likely, vary considerably from laboratory to laboratory.

Mixing studies are usually performed to determine the presence of an inhibitor and exclude the possibility of a coagulation factor deficiency. Abnormal plasma is retested after mixing with an equal volume of normal plasma; the APTT will not correct in the presence of lupus anticoagulant. Even with the most potent anticoagulant, some correction of the clotting time is expected, and laboratories must establish guidelines for defining a significant correction.[13] In our coagulation laboratory the presence of lupus anticoagulant is established when the APTT fails to correct to less than the control mean + 2 SDs.

The question of the specificity of antibodies against phospholipids remains to be resolved. The most widely accepted concept is that antiphospholipid antibodies are cross reactive against acidic phospholipids and potentially against other negatively charged phosphorus-containing molecules. Most of the information has been accumulated, however, with monoclonal antibodies generated from mice prone to systemic lupus erythematosus or patients with systemic lupus erythematosus, or by using polyclonal sera from a small number of patients, usually with systemic lupus erythematosus.[17, 22-24] No doubt most patients produce a cross-reactive antibody, but there is heterogeneity among patients, and some may be producing monospecific antibodies. We reported previously that although most patients produce antibodies that react with both phosphatidylserine and cariolipin, a few patients will produce high titers of antibody that react only with phosphatidylserine.[10]

In a recent publication that reported on patients who were undefined with regard to systemic lupus erythematosus status and were selected for IgG, IgM, or IgA positive reactions against cardiolipin and later tested for IgG antiphosphatidylserine antibodies they calculated a correlation coefficient between IgG anticardiolipin antibodies and IgG antiphosphatidylserine antibodies of 0.84.[25] Although their interpretation was that testing for antiphosphatidylserine afforded little apparent advantage over testing for anticardiolipin, closer analysis of the data shows that more patients were positive for IgG antiphosphatidylserine antibodies than for IgG anticardiolipin antibodies. Two (5.3%) of the patients had elevated assays for IgG antiphosphatidylserine antibodies without IgG anticardiolipin antibodies, whereas none had IgG anticardiolipin antibodies without an accompanying elevation of IgG antiphosphatidylserine antibodies.

In this study most patients have antibodies against both phosphatidylserine and cardiolipin. Five patients, however, have levels >5 SD of IgG antiphosphatidylserine antibodies without corresponding elevations in IgG anticardiolipin antibodies and only one patient has levels >5 SD of IgG anticardiolipin antibodies without elevations in IgG antiphosphatidylserine antibodies. If every patient produced crossreactive antibodies, each patient's serum would be expected to have similar reactivity against both phosphatidylserine and cardiolipin. However, these data suggest that a small group of patients produce antibodies that predominantly react with either phosphatidylserine or cardiolipin and which may not be cross-reactive. There is at least one report of the production in rabbits of antiphosphatidylserine antibodies that did not crossreact with cardiolipin, phosphatidylethanolamine, phosphatidylcholine, phosphatidylinositol, or sphingomyelin.[26] In addition, we have produced a battery of mouse monoclonal antibodies that can be classified into one of three groups: those that are reactive with phosphatidylserine and not with cardiolipin, reactive with cardiolipin and not with phosphatidylserine, and crossreactive with both cardiolipin and phosphatidylserine[16] (Rote et al., unpublished observations).

To understand the biologic effects of antiphospholipid antibodies, their antigenic targets and how the antibody affects biologic activity must eventually be understood. Antiphospholipid antibodies most likely affect alterations in either platelets or endothelial cell-mediated homeostasis of blood clotting.[3, 27] Antibody specificity against cardiolipin, although useful in the diagnosis of the antiphospholipid antibody syndrome, cannot explain the pathophysiology of the disease. It appears highly unlikely that cardiolipin is the target antigen for any of the biologic activities associated with antiphospholipid antibodies. Phosphatidylethanolamine, phosphatidylcholine, and phosphatidylserine are principal components of plasma membranes, whereas cardiolipin has very restricted distribution, localized primarily, if not exclusively, in the inner mitochondrial membrane and not exposed, in a living cell, to circulating antiphospholipid antibodies. For a living cell to be affected in situ by antiphospholipid antibodies, the target antigen must be present in an adequate

concentration in the plasma membrane. Cardiolipin does not meet that criterion.

The mechanism by which antiphospholipid antibodies prolong coagulation in the APTT appears to be through binding to phospholipid within the partial thromboplastin, preventing assembly of the prothrombin-prothrombinase complex, which is necessary for efficient activation of the coagulation cascade.[3,27] Although it has been suggested that affinity-purified anticardiolipin can prolong in vitro coagulation, the actual data have rarely been fully described.[28-30] Exner et al.[30] have been able to separate partially anticardiolipin and lupus anticoagulant activity on an affinity column containing cardiolipin. In addition, cardiolipin is not generally found in the partial thromboplastin used to determine lupus anticoagulant activity by the APTT. With immunologic staining of partial thromboplastin separated by thin-layer chromatography we have determined that the phosphatidylserine constituent is the primary component that reacts with antiphospholipid antibodies from patients with lupus anticoagulant and recurrent pregnancy loss.[16,32] Although determination of antiphosphatidylserine and anticardiolipin may be useful diagnostically, detection of antiphosphatidylserine may be more relevant to understanding the mechanism of this particular autoimmune phenomenon.

It is our conclusion that rigorous testing for lupus anticoagulant activity with well-calibrated and dependable reagents is adequate for detecting most patients with antiphospholipid antibody–associated recurrent pregnancy loss. Most commercially available reagents, however, are too variable to adequately define lupus anticoagulant by the APTT, thus specific phospholipid ELISAs must also be used. Although testing for antibodies against cardiolipin may provide some insight into patients with the antiphospholipid antibody syndrome, testing for antibody against phosphatidylserine identifies some patients who are nonreactive for anticardiolipin and lupus anticoagulant and measures an antibody specificity that is a prime candidate for explaining the pathophysiologic mechanisms of the disease.

We thank Glenn Palomaki of the Foundation for Blood Research for providing statistical analysis and reviewing this manuscript.

Effect of mitral valve prosthetic surgery on the outcome of a growth-retarded fetus

A case report

Luis A. Izquierdo, MD,[a] Ori Kushnir, MD,[a] Karen Knieriem, MD,[b] Jorge A. Wernley, MD,[c] and Luis B. Curet, MD[a]

Albuquerque, New Mexico

Mitral valve prosthetic surgery was performed at 29 weeks' gestation in a woman who had reoperation for a thrombotic mitral valve prosthesis and pulmonary edema. Concomitant severe preeclampsia was also present. During operation fetal bradycardia developed and the fetus died. Because the findings differ from those previously reported with regard to normal pregnancies, their implications are discussed. (Am J Obstet Gynecol 1990;163:584-6.)

Key words: Mitral valve surgery, pregnancy, growth-retarded fetus

Most acquired valvular lesions of the heart are rheumatic in origin, and mitral stenosis is the most common valvular lesion encountered during pregnancy. Morbidity and mortality result from congestive heart failure or arrhythmias.[1] Cardiac surgery can be performed during pregnancy with excellent results for the mother and at relatively low risk to the fetus.[2]

We report a patient with a previous history of mitral valve replacement who had an operation during pregnancy for a thombosed mitral valve and pulmonary edema whose fetus was growth retarded.

Case report

A 33-year old Native American woman, gravida 3, para 3, was seen on Oct. 6, 1988, at 27 weeks' gestation (by her last menstrual period and a 10-week ultrasonogram). She was transferred to the University of New Mexico Hospital because she was thought to have congestive heart failure. She had a history of rheumatic fever with mitral stenosis and aortic insufficiency diagnosed in 1982 when she developed pulmonary edema post partum. She then underwent mitral and aortic valve replacement with Lillehei-Kaster prosthesis (Medical Inc., Inver Grove Heights, Minn.). In 1984 pulmonary edema again developed after a second-trimester pregnancy loss. Since then she had been treated with coumadin until approximately 12 weeks

Fig. 1. Presence of decelerations during operation.

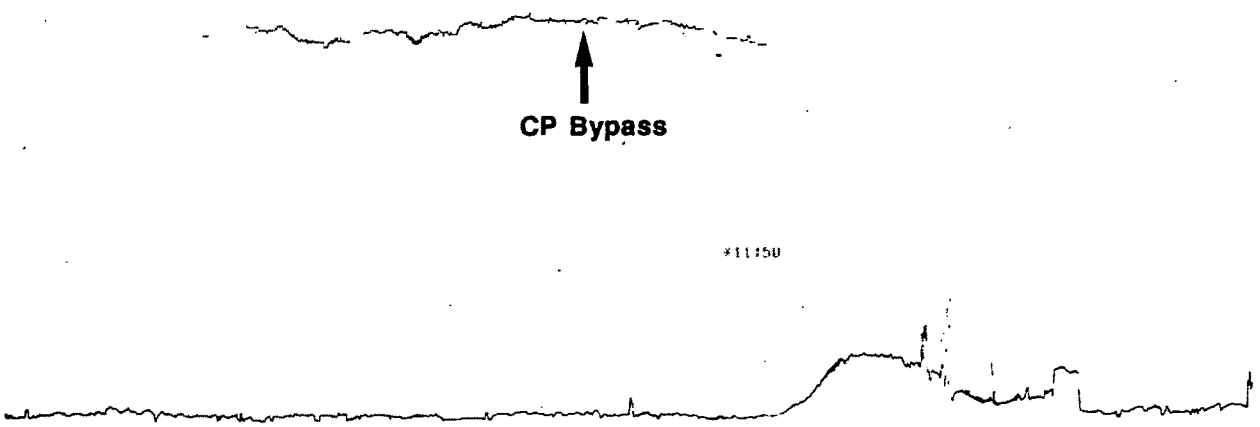

Fig. 2. Patient connected to cardiopulmonary bypass and disappearance of fetal heart rate.

into her third pregnancy, when her medication was changed to subcutaneous heparin. On admission to the University of New Mexico Hospital, she had two-pillow orthopnea and reported progressively worsening shortness of breath on exertion since the first trimester of pregnancy. Blood pressure was 150/110 mm Hg and results of a urinalysis showed 8 gm of protein in a 24-hour collection. Chest x-ray films revealed no evidence of acute disease. A transthoracic echocardiogram showed moderate mitral stenosis, mild aortic insufficiency, and mild left ventricular dysfunction with no apparent thrombus. Obstetric ultrasonography revealed all growth parameters consistent with a 24-week fetus with an estimated fetal weight of 580 gm. This parameter was below the 10th percentile for weight, consistent with intrauterine growth retardation.

The patient was managed conservatively with bed rest and close surveillance. The hypertension responded to bed rest and the patient did not require antihypertensive medication. Proteinuria remained without significant change on repetitive 24-hour urine collections. Laboratory studies remained unremarkable except for elevated serum uric acid and serum creatinine levels. The patient was maintained on therapeutic heparin by continuous intravenous infusion. Two weeks after admission, pulmonary edema developed, for which she was treated and stabilized. A transesophageal echocardiogram revealed significant mitral stenosis with a mitral valve area <0.7 cm. It could not be determined whether this represented tissue overgrowth or a thrombus around the mitral valve. It was decided to proceed with open heart surgery and replacement of the mitral valve with the patient under fentanyl anesthesia. The fetal heart tones were continuously monitored. The left atrium was open longitudinally, and the mitral valve prosthesis revealed thrombotic aggregates occupying the left atrium, measuring 4.5 × 3.5 × 0.8 cm. The aortic valve prosthesis was inspected through a dental mirror introduced into the left ventricle and was thought to be normal. The mitral valve annulus measured only 27 mm; therefore a 27 mm St. Jude Medical prosthesis (St. Jude Medical, Inc., St. Paul, Minn.) was used. The prosthesis sat well in the annulus and all sutures were tied without difficulty. Unrestricted motion of both leaflets was carefully con-

firmed. The patient was weaned from cardiopulmonary bypass without difficulty.

One hour after the operation was begun, fetal heart rate decelerations (Fig. 1) were noted. Two minutes after the cardiopulmonary bypass pump was established at 33° C and high-flow–high-pressure perfusion, the fetal heart activity on the monitor was lost (Fig. 2) and fetal death was confirmed by ultrasonography. The cardiac surgery was completed without problems. The patient's postoperative course was unremarkable. Labor was induced with oxytocin 1 day after operation and a stillborn male fetus (640 gm) was delivered. Parents refused autopsy of the fetus. A tubal sterilization was performed 2 days post partum with the mother under general anesthesia.

Comment

Previous studies of fetal responses to cardiopulmonary bypass have found no relationship between gestational age and fetal mortality. Pregnant patients undergoing cardiopulmonary bypass have better fetal outcomes when high-flow–high-pressure normothermic perfusion is used. With this technique, fetal mortality and morbidity associated with the operation are considerably diminished. Maternal mortality has been reported up to 2%, whereas perinatal loss is approximately 10%.[1,2]

Fetal bradycardia during cardiopulmonary bypass has been observed consistently.[2] However, the fetal heart rate returns to baseline after discontinuation of cardiopulmonary bypass or an increase in blood flow from the pump. Our patient's clinical situation differs from that in patients in other studies in two ways. First, the fetus had intrauterine growth retardation, and second, the mother had severe preeclampsia. There are no reports on the effects of cardiopulmonary bypass on mothers with preeclampsia who have growth-retarded fetuses.

Clinical experience has demonstrated that antepartum fetal assessment can have a significant impact on the frequency of antenatal fetal deaths. In most high-risk pregnancies it is preferable to allow the fetus to remain in utero as long as possible. To decrease the likelihood of unnecessary premature interventions, tests of fetal well-being are used and delivery of a premature infant would be accomplished only if these tests suggest fetal compromise.

Delivery of an infant whose mother has mitral stenosis and pulmonary edema presents a serious problem. Hemodynamically, a defect exists that obstructs the left atrial outflow, which in turn decreases the cardiac output and elevates pressure in the left atrium and pulmonary vasculature. Distention of the left atrium with consequent decreased blood flow predisposes such patients to arrhythmias, such as atrial fibrillation, and to systemic thrombus formation. Cardiac output in pregnancy reaches its peak at approximately 30 weeks and is maintained until term. A patient with an already compromised left heart is at increased risk as pregnancy advances, increasing the incidence of heart failure and maternal mortality late in pregnancy and during the puerperium.

Open heart surgery with valve replacement should be considered in patients with heart failure who do not respond to medical treatment.[1,2] Options considered before operation for this patient included continuation of expectant fetal management as long as the mother tolerated the pregnancy well. This was done until the maternal heart failure was unremitting. The other option considered was to perform heart surgery and perform a cesarean section at the same time. This option was discarded because with the known perinatal mortality risk of 10%, the outcome for this fetus at 29 weeks was probably better if it remained undelivered.[1,2]

On the basis of our experience with this case, it would appear that a severely growth-retarded fetus with lack of uteroplacental reserve may better be delivered before the mother has cardiopulmonary bypass surgery since the likelihood of fetal survival during maternal cardiopulmonary bypass surgery appears to be remote. However, cardiopulmonary bypass may not have been the sole cause of fetal death. Coumadin treatment during the first trimester could have contributed to the result. Hall et al. have shown that such therapy may cause the fetal warfarin syndrome. In addition, the patient had severe preeclampsia and, as already described, the fetus was growth retarded. Because these findings are significantly different from those reported in previous studies, this case report supports the importance of the complete evaluation of pregnant patients with acquired heart disease during pregnancy.

Despite these factors it is our opinion that the use of cardiopulmonary bypass in pregnant patients with evidence of uteroplacental insufficiency is fraught with grave changes for the fetus. Thus it would seem reasonable in such situations to deliver the fetus before cardiopulmonary bypass is started.

Laparoscopic diagnosis and treatment of interstitial ectopic pregnancy: A case report

Resad Pasic, MD, and Walter M. Wolfe, MD
Louisville, Kentucky

The laparoscope was used to diagnose and treat an interstitial pregnancy that had been overlooked on ultrasonographic examination. (Am J Obstet Gynecol 1990;163:587-8.)

Key words: Interstitial pregnancy, ectopic pregnancy, laparoscope

Interstitial implantation is one of the rarest sites of ectopic gestation. To our knowledge, this is the first published report of the laparoscopic treatment of an interstitial pregnancy.

Case report

The patient, a 25-year-old women, gravida 3, para 1, was first seen at the clinic with a 6-week history of amenorrhea and steady bleeding but without any pain. Initial assay result of β-subunit of human chorionic gonodotropin (β-hCG) was 4034 mIU/ml. Vaginal probe ultrasonography revealed an empty uterine cavity and a sonolucent area, 2.7 × 3.2 cm, with irregular borders in the right adnexa. She had no history of pelvic inflammatory disease. In 1981 she underwent a left salpingo-oophorectomy for removal of a fibrothecoma in the left ovary and a curettage in 1983 because of possible spontaneous, first-trimester abortion. In 1987 she underwent a curettage followed by a laparoscopic, right, linear salpingostomy for removal of a probable ectopic pregnancy.

The patient was admitted to the hospital 2 days after her clinic visit. The β-hCG level was 4400 mIU/ml; blood pressure, 114/80 mm Hg; pulse, 60 beats/min; temperature, normal; hematocrit, 39.1%; and hemoglobin, 12.9 gm/dl. The result of general physical examination was unremarkable. The abdomen was soft and distended with diffuse tenderness, and bowel sounds were absent. Pelvic examination disclosed evidence of bleeding; the cervix was long and closed, and the uterus was midplane, 6 to 8 weeks' size. No adnexal mass was palpated.

We performed a curettage that produced no tissue or placental villi. Because we suspected an ectopic pregnancy, we performed a diagnostic laparoscopy. Chromotubation, performed to identify a fistulous tract or to confirm patency, showed a nonpatent right tube and no dye spilling into the abdomen. Laparoscopic examination revealed multiple adhesions covering the left cornual portion of the uterus and a dilated area near the fimbriated end of the right tube suggestive of an ectopic pregnancy. This was removed by endocoagulation of the mesosalpinx and proximal end of the tube and sent for pathologic examination, the results of which were negative. Removal of the adhesions covering the left cornu revealed a 1 to 2 cm protrusion of the uterine wall that appeared to contain blue dye. After vasopressin solution was injected, a left cornual incision, 1 cm long, was performed to remove the products of conception, as confirmed by pathologic examination. Hemostasis was achieved by endocoagulation.

After the surgical procedure, we carefully examined the ultrasonogram and discovered a sonolucent area in the left cornual region that had been overlooked previously (Fig. 1).

Eight months after the operation, the patient has had no complications related to the procedure.

Comment

Although nontubal ectopic pregnancies represent <5% of all ectopic pregnancies, they account for approximately 20% of the fatalities attributed to ectopic gestations.[1] Difficulty in diagnosing these rare ectopic pregnancies may contribute to their high rate of complications.

The diagnosis of interstitial pregnancy is difficult because of the nonspecific symptoms. The most common symptoms, amenorrhea, pelvic pain, and bleeding, are similar to those encountered with other clinical conditions. In addition to history and physical examination, ultrasonography, and β-hCG assay, laparoscopy is of proved value in confirming the diagnosis of ectopic pregnancy. Laparoscopy, however, does have a 2% to 5% false-positive or false-negative rate. Early ultraso-

nographic diagnosis of an interstitial pregnancy is quite difficult and, as happened in this case, the pregnancy can easily be overlooked.

In addition to its value as a diagnostic tool, laparoscopy coupled with pelviscopic surgical techniques can be used to treat ectopic pregnancy. We were able to use it to successfully treat an early, unruptured, interstitial pregnancy.

A vesicovaginal fistula and intravesical foreign body

A rare case of the neglected pessary

Irwin Goldstein, MD, Gilbert J. Wise, MD, and M. Leon Tancer, MD
Brooklyn, New York

A case of neglected pessary is presented. After erosion through the anterior vaginal and bladder walls the device came to rest entirely within the bladder. Surgical management of removal of the pessary and repair of the resulting vesicovaginal fistula are described. Appropriate use of supportive pessaries as well as complications of misuse and neglect are discussed. (Am J Obstet Gynecol 1990;163:589-91.)

Key words: Pessary, vesicovaginal fistula, genital prolapse

A literature search that failed to produce a prior instance in which an entire intravaginal supportive device was found within the urinary bladder provoked this case report.

Case report

An 82-year-old white, multiparous woman complained of constant urinary leakage for 6 weeks. She had undergone a right nephrectomy after diagnosis of renal cell carcinoma 5 years previously and 29 months previously had been treated for cystocele by placement of an intravaginal supportive device. She had seen no physician since.

At pelvic examination urine was seen flowing from the vagina. The knob of a Gelhorn pessary could be felt and seen high in the posterior vagina. Gentle traction on the knob indicated marked impaction. Cystoscopy revealed the base of the device to be in the bladder. Cystography (Figs. 1 and 2) showed the device within the bladder and the vagina outlined by dye, implying the presence of a vesicovaginal fistula. At examination with the patient under anesthesia the device could no longer be felt in the vagina. Instead, it was felt through a 6 cm anterior vaginal wall defect to be in the bladder.

A suprapubic, extraperitoneal, transvesical approach through a low transverse incision was used to remove the foreign body, a Gelhorn pessary with a 2¾ inch base. A 6 cm vesicovaginal defect was observed to be 1 cm away from the left ureteral orifice. After passage of a feeding tube up to the left kidney, the fistula was circumcised at the junction of bladder mucosa and vaginal epithelium and the bladder was dissected free from the underlying vagina. The vaginal defect was closed with a single running suture and, after freshening the edges of bladder mucosa, the bladder defect was closed with figure-of-8 sutures. The cystotomy site was closed in two layers while the feeding tube, a cystotomy catheter, and a drain from the space of Retzius were exteriorized.

A cystogram performed 2 weeks after operation showed the bladder to be intact. There was no dye seen in the vagina, and the suprapubic tubes were removed. One month later the patient was voiding well and the vagina was well healed; there was no cystocele.

Comment

The elderly patient with genital prolapse has long been known to tolerate vaginal extirpative and reconstuctive surgery with minimal morbidity and mortality.[1] Nevertheless, supportive intravaginal devices (pessaries) continue to have a place in the management of such disorders.

The temporary use of a pessary during the period before definitive operation is strongly recommended. It enables the patient to enjoy a degree of comfort during the time required to undergo medical evaluation and to overcome medical complications in preparation for operation. In addition, it is not unusual for exteriorized vaginal epithelium to be atrophic, ulcerated, dehydrated, and of elephantoid consistency. A pessary provides internalization and allows time to treat the epithelium with estrogen so that tissues are better prepared at the time of operation.

A pessary may be used as definitive therapy for genital prolapse because of a patient's advanced age, medical complications that preclude surgical intervention, or commonly, the patient's refusal to undergo surgery.

Whether used as a temporary or definitive measure, a misused or neglected pessary is dangerous. Common complications include severe ulceration of the vagina and incarceration that necessitate the use of general anesthesia for removal of the device. In the past we

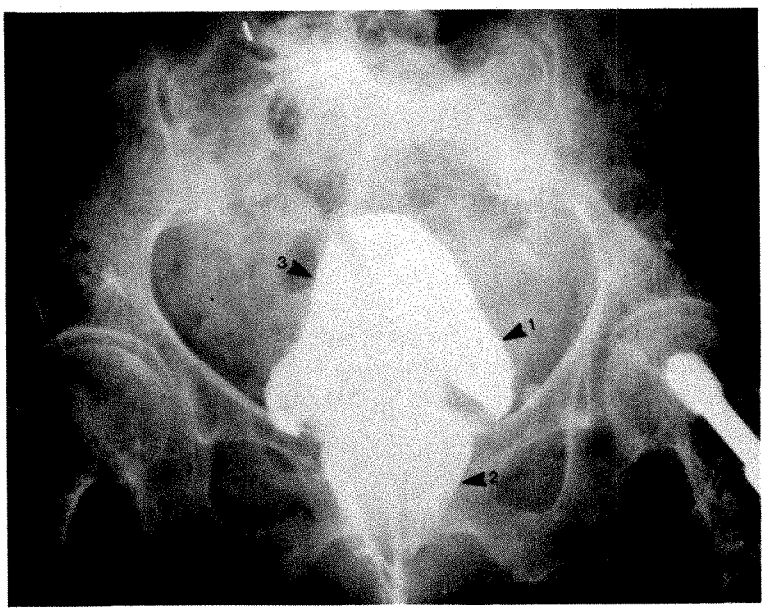

Fig. 1. Cystogram (anteroposterior view).

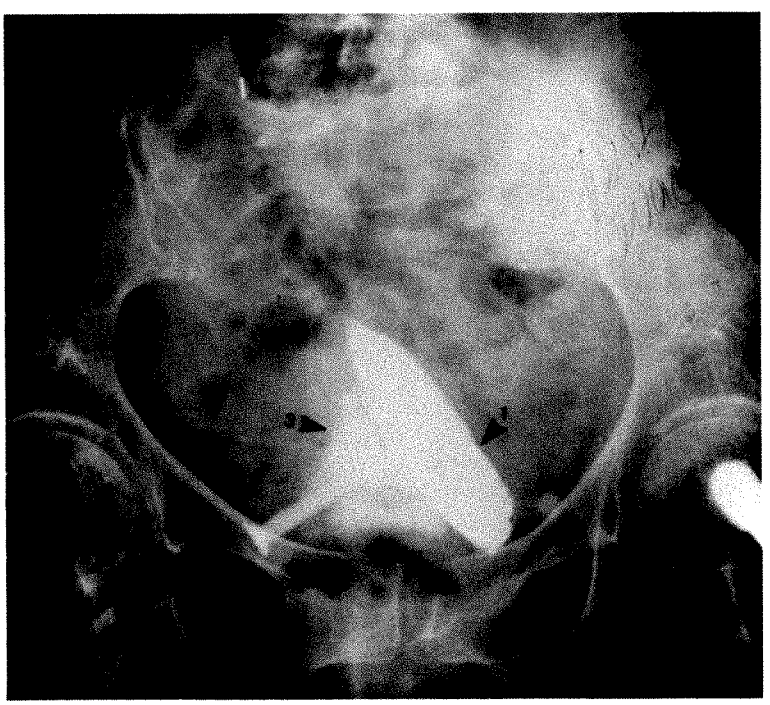

Fig. 2. Postevacuation cystogram. *1*, Gelhorn pessary within bladder; *2*, dye in vagina; *3*, dye in bladder.

have seen both a rectovaginal fistula and a vesicovaginal fistula in association with pessary misuse or neglect and are aware of a report in which an ulcerating pessary caused simultaneous rectovaginal and vesicovaginal fistulas.[2] To avoid misuse of a pessary the clinician must make certain that the patient and her family or her institutional support staff understand the importance of frequent, periodic examinations during which the device is to be removed, the vagina cleansed, and the vaginal epithelium inspected for evidence of pressure trauma. Unfortunately, such patients are likely to be elderly, forgetful, physically separated from family,

or institutionalized. Patient neglect then supersedes proper treatment and the device is all but forgotten, with a resulting complication as occurred in our case.

When the pessary in our patient was removed, the question arose as to whether closure of such a large vesicovaginal fistula should be done immediately or postponed to allow involution of the lesion with subsequent transvaginal repair. Our concern was that failure of the transvesical repair might result in a lesion larger than the original with encroachment on the sole remaining ureter. In addition, one of us (M. L. T.) has resorted previously to an abdominal approach in only four of 140 patients with a variety of vesicovaginal fistulas, so that a transvaginal approach seemed reasonable. Our decision for immediate repair was made based on the fact that when viewed transvesically, the fistula borders appeared neither macerated nor infected and the stented left ureteral orifice was clearly in view.

In summary, a rare complication of the neglected pessary and the management of that complication are reported. The results of misuse and neglect of pessaries are stated, and the appropriate use of a pessary is described. The reasons for immediate repair of the complicating vesicovaginal fistula are discussed.

Malignant leiomyomatosis peritonealis disseminata

George J. M. Akkersdijk, MD,[a] Peter K. Flu, MD, PhD,[a] Raymond W. M. Giard, MD, PhD,[b] Mattheus van Lent, MD, PhD,[c] Henk C. S. Wallenburg, MD, PhD[d]

Rotterdam, The Netherlands

Leiomyomatosis peritonealis disseminata is a rare condition characterized by the presence of multiple intraabdominal nodules that consist of benign smooth muscle. We found 42 documented cases in the literature. Malignant degeneration appears to be extremely rare. We describe the second case with proved malignancy. (Am J Obstet Gynecol 1990;163:591-3.)

Key words: Leiomyomatosis, leiomyosarcoma, peritoneum

Leiomyomatosis peritonealis disseminata is a rare condition. A search of the literature revealed only 42 documented cases. In one case malignant degeneration occurred. This report presents the second case of malignant leiomyomatosis peritonealis disseminata.

Case report

A 25-year-old, white nulligravid woman was referred because of acute right lower abdominal pain. She did not have nausea, vomiting, or abnormal weight loss. She had regular menstrual periods without the use of oral contraceptives. Appendectomy had been performed 2 years previously. The right lower abdominal quadrant was tender on palpation. Gynecologic examination revealed a normal-sized uterus with an anterior solid nodule and a tender, only slightly mobile mass on the right side. Both tumors had an estimated diameter of approximately 7 cm. General blood and urinalysis gave unremarkable results, except for an erythrocyte sedimentation rate of 22 mm in the first hour. Ultrasonographic examination revealed a pelvic tumor with solid and cystic parts on the right side, but not attached to the uterus. The anterior wall of the uterine corpus showed a small solid nodule. Laparotomy was performed after induction of general anesthesia, and two nodular tumors were found to be present, each with a diameter of approximately 6 cm. One tumor was attached to the ascending colon, and the other tumor was situated on the anterior surface of the uterine corpus. The omentum, colon, and small intestine were scattered with firm, gray-white subperitoneal nodules, varying in size between a few millimeters to 2 cm. The ovaries showed no abnormalities. Microscopic examination of frozen biopsy specimens revealed clusters of spindle-shaped smooth muscle cells, without histologic features of malignancy. The two large tumors

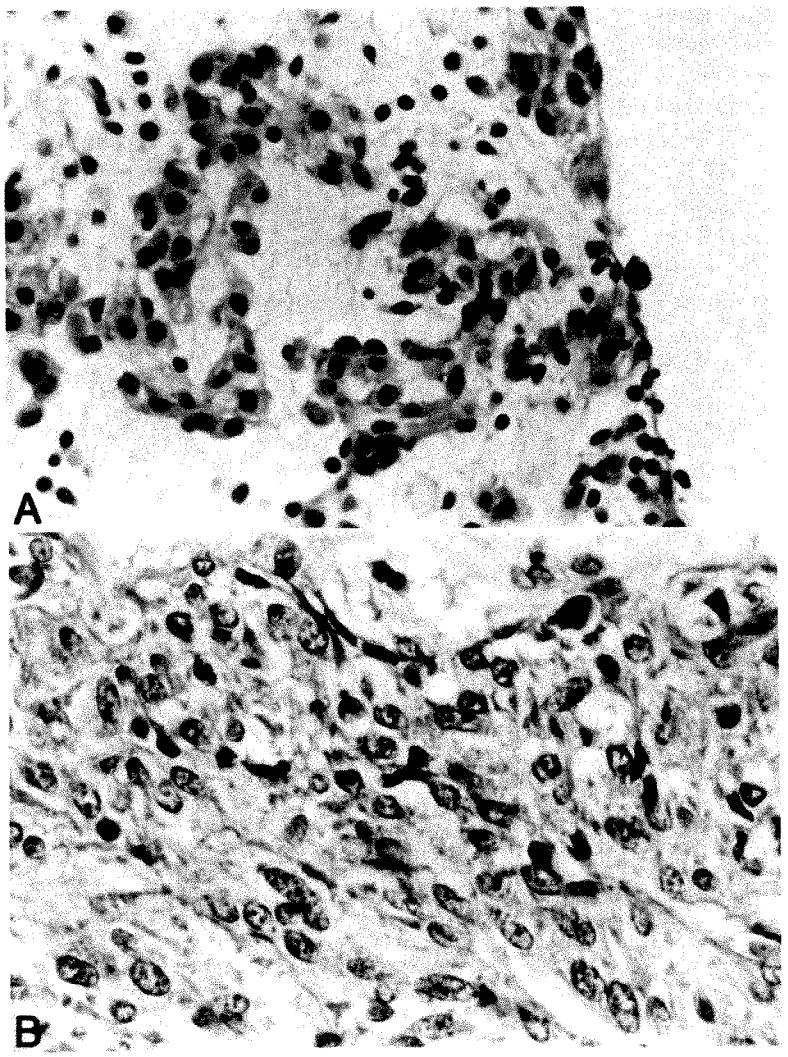

Fig. 1. A, Diagnosed as leiomyomatosis peritonealis disseminata. (Hematoxylin and eosin stain; original magnification ×480.) **B,** Sarcomatous degeneration 1 year later. (Masson trichrome stain; original magnification ×480.)

were removed and the uterus and ovaries were left behind. Histologic examination of the tumors showed fusiform smooth muscle cells, without abnormal mitotic activity or atypical nuclei, in decidualized connective tissue. A diagnosis of leiomyomatosis peritonealis disseminata was made (Fig. 1, *A*).

Six months later the patient had no complaints. Gynecologic examination revealed no abnormalities. On laparoscopic inspection no change in the size or number of the nodules was apparent. Biopsy specimens were taken from some of the nodules, which on histologic examination showed the same features as those observed in the tumors removed earlier. One year after laparotomy, the patient was seen at follow-up examination without any clinical signs or symptoms. However, a solid tumor of approximately 10 cm diameter was felt in the right lower abdominal quadrant, and vaginal and rectal palpation revealed a firm mass in the cul-de-sac. A second laparotomy was performed and multiple tumors varying in size from 0.5 to 10 cm were found scattered throughout the abdominal cavity. The uterus and ovaries were covered in dense adhesions. Nodules were felt on the dome of the liver.

Histologic examination of biopsy specimens showed marked cellularity and numerous mitoses. A diagnosis of poorly differentiated leiomyosarcoma was made (Fig. 1, *B*), and it was decided to refrain from further attempts to surgically remove the tumors. The patient refused chemotherapy and was treated with a luteinizing hormone–releasing hormone agonist. The abdominal tumors increased in size and the patient's condition progressively deteriorated. She died 22 months after the initial diagnosis of leiomyomatosis peritonealis disseminata; autopsy was refused.

Comment

Leiomyomatosis peritonealis disseminata is a rare disorder of unknown cause. We found 41 documented cases in the literature since the first case was reported

in 1952.[1] Patients with leiomyomatosis peritonealis disseminata are exclusively female. The average age at the time of diagnosis is 37 years (22 to 55 years). In one reported case leiomyomatosis peritonealis disseminata was found at autopsy in a 69-year-old woman. There seems to be a predisposition for blacks (50% of those whose race was reported). Symptoms of lower abdominal pain and menorrhagia occurred, but patients were often asymptomatic, in which case the diagnosis was made at cesarean section (nine patients), laparotomy for other reasons (eight patients), or laparoscopic tubal ligation (two patients). At laparotomy the macroscopic findings may simulate malignancy.

Multiple subperitoneal gray-white masses with a firm to rubbery consistency, varying in size from 0.1 to 10 cm were found on the parietal peritoneum, uterus, omentum, and the mesentery in all patients. On microscopic examination the lesions appear to consist of subperitoneal smooth muscle proliferations. In contrast to leiomyosarcoma there is little mitotic activity.[1] In some cases a decidual reaction, fibroblasts, and myofibroblasts were found in the nodules. Because of this it has been suggested that leiomyomatosis peritonealis disseminata is a fibrotic reaction to deciduosis rather than smooth muscle proliferation.[1]

The pathogenesis of leiomyomatosis peritonealis disseminata is unknown, but a hormonal factor may be involved. More than half the reported patients were pregnant or taking oral contraceptives at the time of diagnosis. Disseminated leiomyomatosis has been induced in animals by means of administration of estrogens, and regression occurred after cessation of the stimulation.

Regression of the tumors has also been described after surgical castration, withdrawal of oral contraceptives, and post partum. A search of the literature revealed a single report of malignant degeneration in leiomyomatosis peritonealis disseminata. In an apparently healthy 27-year-old gravida 1 woman, leiomyomatosis peritonealis disseminata was found at cesarean section. Six months later the patient was seen with a rapidly growing pelvic tumor and diffuse bone metastases. Hysterectomy, salpingo-oophorectomy, and resection of most of the pelvic tumors were performed. Pathologic findings were characteristic of small spindle cell sarcoma. Despite combination chemotherapy the patient died within 2 years after the laparotomy.[2]

Leiomyomatosis peritonealis disseminata appears to be a rare condition that usually runs a benign course. There are no firm guidelines in the literature with regard to the management of these patients. Although we report the second documented case of malignant degeneration, we believe that an aggressive approach to leiomyomatosis peritonealis disseminata is not warranted.

An abdominal pregnancy 10 years after treatment for pelvic tuberculosis

Tekin Durukan, MD,[a] Bülent Urman, MD,[a] Hakan Yarali, MD,[a] Ünser Arikan, MD,[b] and Ömer Beykal, MD[c]

Ankara, Turkey

An abdominal pregnacy after treatment for female genital tuberculosis is presented. Early treatment after the diagnosis of female genital tuberculosis may restore fertility in the rare patient. Chemotherapy is the cornerstone of therapy. Ectopic pregnancies are common and should be ruled out to avoid catastrophic results. (Am J Obstet Gynecol 1990;163:594-5.)

Key words: Pelvic tuberculosis, abdominal pregnancy

Intrauterine pregnancy is rare after genital tuberculosis. It may occur occasionally if the disease is diagnosed and treated in its very early stage. Ectopic pregnancies have been reported after antituberculous therapy and after reconstructive surgery for occlusions of the oviducts because of this condition.[1] An abdominal pregnancy after treatment for female genital tuberculosis is presented and discussed.

Case report

A 38-year-old woman who had been infertile for 10 years reported to the emergency department complaining of abdominal pain, nausea, and vomiting. She stated that she was 13 weeks pregnant according to her last menstrual period. The result of a urine pregnancy test was positive, and the patient complained of lower abdominal pain and vaginal bleeding for the past week.

During an infertility workup 8 years ago hysterosalpingography revealed a bilateral tubal block and signs compatible with female genital tuberculosis. Biopsy from the endometrium was reported as granulomatous endometritis. She received multiple-agent antituberculous therapy (isoniazid 300 mg/day; ethambutol 1000 mg/day; and rifampin 600 mg/day) for 12 months.

Physical examination disclosed an abdomen that was mildly distended with rebound tenderness in lower quadrants. A left-sided tender mass was palpated bimanually.

Ultrasonographic examination of the pelvis revealed an empty uterus and a gestational sac occupied by a 13-week embryo with positive cardiac activity adjacent to the uterus in the pouch of Douglas (Fig. 1). A presumptive evidence of ovarian or abdominal pregnancy was made.

At laparotomy it was seen that the sac and the embryo measuring 12 × 10 × 10 cm occupied the pouch of Douglas with the placenta attached to the posterior leaf of the broad ligament and partially to the Douglas peritoneum. The placenta was partially separated and there was approximately 300 ml of blood filling the Douglas pouch. The tubes were intact with no evidence of uteroperitoneal fistula, and the ovaries on both sides were normal with a leaking corpus luteum occupying the left ovary. A left salpingo-oophorectomy was performed, removing the placenta totally with partial dissection of the Douglas peritoneum; the bleeding sites were cauterized.

The pathologic examination revealed a normal tube with calcifications in the muscularis layer. There were no chorial elements in the ovary and the sac showed no evidence of ovarian tissue. A diagnosis of abdominal pregnancy was made.

Comment

Primary abdominal pregnancy is rare and represents 1.6% of all ectopic pregnancies. Criteria first set by Studdiford should be met to make the diagnosis.[2] The outcome of pregnancy is usually fetal death or placental separation with intraperitoneal bleeding. Ultrasonography is useful in diagnosis of the condition, especially if the uterus is empty and both ovaries are visible. Recurrent abdominal pain in an infertile woman should alert the clinician to the probability of abdominal pregnancy in addition to more likely diagnoses, such as recurrent pelvic inflammatory disease, including female genital tuberculosis, tubal ectopic pregnancy, and threatened abortion. Prompt termination is necessary once the diagnosis is made.

Female genital tuberculosis should be treated medically after the diagnosis. Operation should not be the

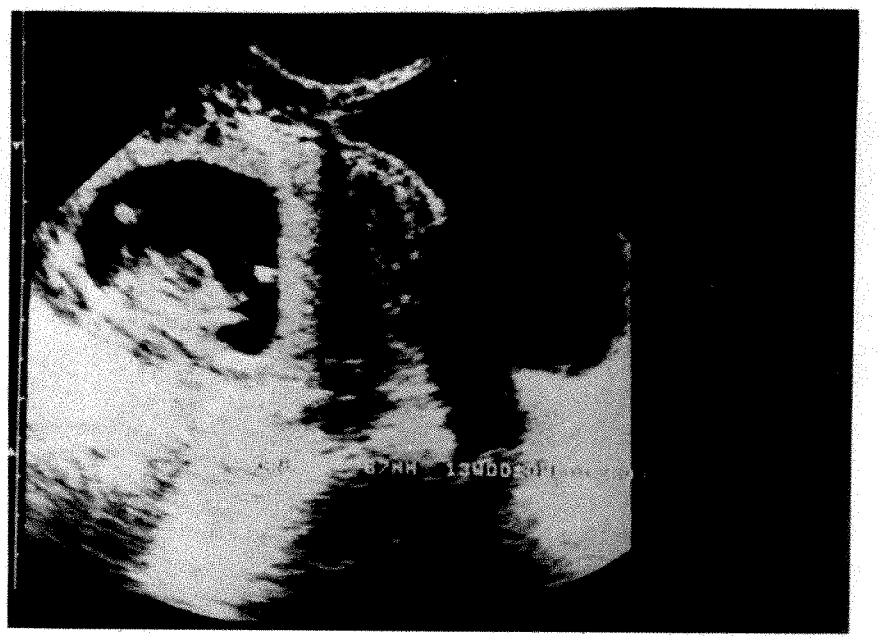

Fig. 1. Pelvic ultrasonogram of the patient reveals an empty uterus and a gestational sac localized in the pouch of Douglas.

initial mode of therapy because of the possibility of activating latent disease; however, if use of the antituberculous drugs are not successful and symptoms or tuboovarian masses remain after 1 year, operation should be considered with use of an additional drug not used in initial treatment. Hysterosalpingogram can be diagnostic if the typical signs are seen. Endometrium is involved in 50% of cases. Early diagnosis and therapy may restore fertility, although ectopic pregnancies and abortions are more common than successful intrauterine pregnancies. In a 31-year study of 1436 cases of female genital tuberculosis, only four pregnancies (two localized ectopically to the tubes) have been reported.[1]

A patient with a history of female genital tuberculosis should be followed up indefinitely. Their pregnancies should be considered high risk, and ectopic nidation, which may occur even after a long period, should be ruled out to avoid catastrophic results.

Papillary cystadenoma of the broad ligament in von Hippel-Lindau disease

William T. Korn, MD,[a] Stefan C. Schatzki, MD[a] Anthony J. DiSciullo, MD,[b] and Robert E. Scully, MD[c]

Cambridge and Boston, Massachusetts

We present radiologic-pathologic correlation in a case of von Hippel-Lindau disease diagnosed on the basis of the discovery of papillary cystadenoma of wolffian duct origin, a rare calcified tumor of the broad ligament that was visible on the abdominal radiograph. (AM J OBSTET GYNECOL 1990;163:596-8.)

Key words: Cystadenoma, broad ligament, von Hippel-Lindau disease, inherited diseases

von Hippel-Lindau disease is a potentially fatal disorder with an autosomal dominant pattern of inheritance. We report a case in which the first clinical manifestation of this disease was a distinctive rare bilateral tumor of the broad ligament.

Case report

A 35-year-old, asymptomatic, white woman was evaluated for right lower-quadrant abdominal pain. On pelvic examination the right ovary was slightly enlarged. Neurologic examination and routine laboratory tests, including urinalysis, were normal. A radiograph of the abdomen revealed a curvilinear calcification in the right pelvis (Fig. 1). Ultrasonography demonstrated a sonolucent mass containing an echogenic region in the right adnexa. At operation the fallopian tubes and bilateral paratubal masses were excised. Pathologic examination revealed a 5 cm bilobed, cystic right paratubal mass with focal calcification of its wall. Dissection of the mass disclosed two locules, 3.2 and 2 cm, con-

Fig. 1. Detail from abdominal radiograph demonstrates crescentic calcification in the pelvis *(arrows)*. Differential diagnosis includes dermoid cyst and mucinous cystic tumor.

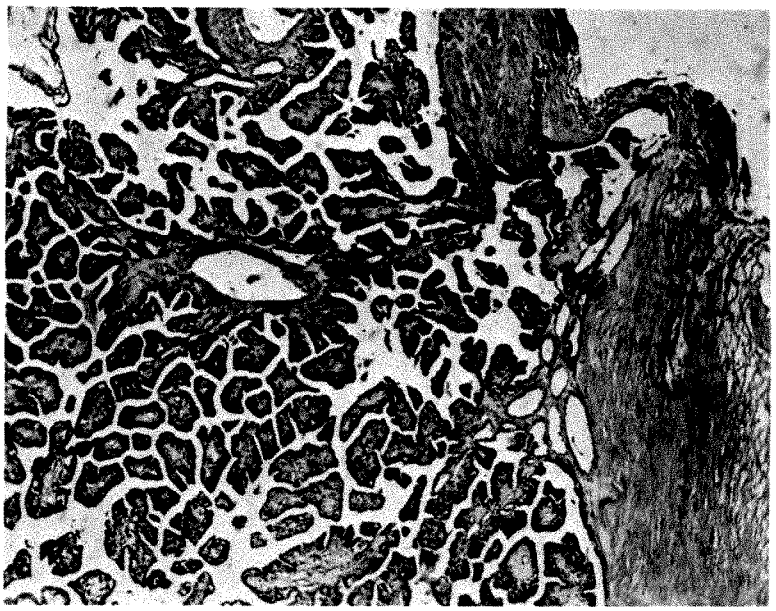

Fig. 2. Papillary cystadenoma consisting of small papillae lined by cuboidal epithelial cells. The wall of the cyst is thickened and hyalinized. (Original magnification × 125.)

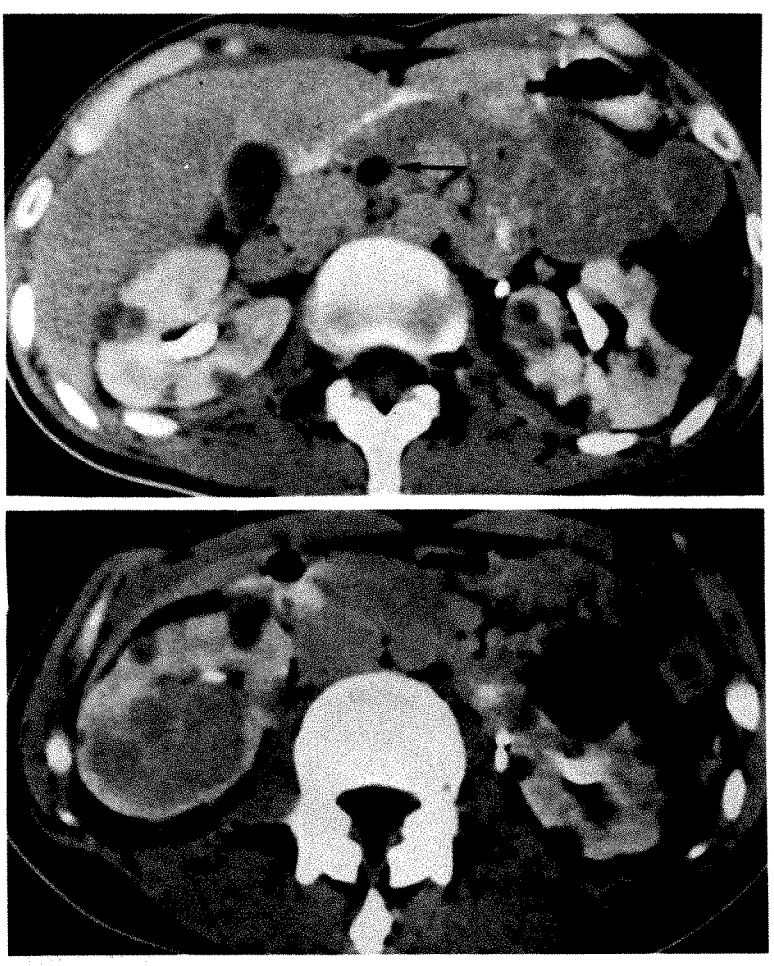

Fig. 3. Axial computed tomography of the abdomen demonstrates numerous cystic and solid lesions in the kidneys and a small pancreatic cyst *(arrow)*.

taining polypoid structures with papillary surfaces. The left paratubal mass was a 2 cm unilocular cyst otherwise similar to the right-sided mass.

Microscopic examination revealed that the cysts contained polypoid masses characterized by an intricate network of spaces with a complex papillary pattern (Fig. 2). The cores of the papillae were composed of cellular to hyalinized to edematous connective tissue. The papillae were lined by bland-appearing cuboidal epithelial cells with central nuclei. The cytoplasm was densely eosinophilic or showed surface vacuolizaton; no cilia were observed. The walls of the cysts were composed of fibrous tissue with patchy hyalinization and focal calcification on the right side. The fallopian tubes appeared normal. A diagnosis of papillary cystadenoma of wolffian duct origin, highly suggestive of von Hippel-Lindau disease, was made.

Ophthamologic examination was normal. Computed tomography of the brain demonstrated three homogeneously enhancing cerebellar lesions consistent with hemangioblastomas. Computed tomography of the abdomen revealed bilateral renal solid and cytic masses and a small pancreatic cyst (Fig. 3). Bilateral partial nephrectomies were performed with the removal of multiple renal cell carcinomas.

Comment

The findings associated with von Hippel-Lindau disease include hemangioblastomas, retinal angiomas, renal cell carcinomas, renal, pancreatic, hepatic, and splenic cysts, pheochromocytomas, and less commonly, adenomas of the liver, pancreas, epididymis, and kidneys.

In men, papillary cystadenoma of the epididymis is an uncommon tumor that is considered almost diagnostic of von Hippel-Lindau disease when bilateral. It occurs in 10% of men with the disease.[1] A histologically identical tumor in women is the papillary cystadenoma of the broad ligament of wolffian duct origin,[1] only three of which have been reported. One was bilateral and the other two apparently unilateral; each was associated with von Hippel-Lindau disease.[1,2] Radiologic findings were described in one case and included curvilinear calcifications in an adnexal mass on computed tomography. In none of the cases was this tumor the first clinical manifestation of the disease; in two cases, von Hippel-Lindau disease had been evident for 20 or more years before presentation of the paraovarian mass.

The classic lesions of von Hippel-Lindau disease were clinically silent in this case. The detection of a cystic calcified pelvic mass led to the diagnosis of von Hippel-Lindau disease. This expedited the detection of renal and cerebellar tumors, allowing the performance of a kidney-sparing operation and close monitoring of the cerebellar lesions. In addition, screening of the patient's family will hasten the diagnosis of any additional cases of this potentially fatal illness.

Anencephalics as organ donors

F. Andre Van Assche, MD, PhD
Leuven, Belgium

Anencephalics can be divided into a large group without a functional hypothalamohypophysial system and a smaller group with a functional hypothalamohypophysial system. Anencephalics of the first group do not live more than a few hours, whereas the anencephalics of the second group can live up to 3 days. Those with a functional hypothalamohypophysial system have shown pain reaction. In anencephalics without a functional hypothalamohypophysial system, the endocrine pancreas does not reach full maturation and the use of these glands for islet transplantation can be questioned. (Am J Obstet Gynecol 1990;163:599-600.)

Key words: Anencephaly, transplantation, endocrine pancreas

The use of anencephalic newborns as organ donors is currently of interest.[1] An important ethical question remains regarding at what time after birth organs can be used, without damage of these organs. Although we do not as yet have any personal practical experience in transplantation from such donors, it is important to relate our data on these cases collected 20 years ago in northern Ireland. The main purpose was the study of the fetal endocrine pancreas.[2] In nearly all cases diagnosis of anencephaly was made before birth; induction of labor was performed by rupture of the membranes associated with oxytocin infusion. In resistant situations hypertonic saline solution was injected into the amniotic fluid.

Because we needed fresh material only anencephalics who were born alive were used. An autopsy was performed after death was confirmed by a pediatrician of the local hospital. In connection with our experimental design only anencephalics born after 30 weeks' gestation were used. The results of our previous studies[2] had clearly demonstrated that a functional hypothalamohypophysial system was necessary for complete morphologic and functional maturation of the fetal endocrine pancreas.

Changes as seen in newborns of mothers with diabetes were only present in anencephalics with a functional hypothalamohypophysial system. Islet hypertrophy, B cell hyperplasia, and hyperinsulinism were not found in anencephalics without a functional hypothalamohypophysial system born to a mother with diabetes.[2] We collected data on 33 cases. The criteria for the presence of a functional hypothalamohypophysial system were as follows: (1) the macroscopic presence of a hypothalamohypophysial structure, (2) the presence of a fetal adrenal cortex by microscopic examination, and (3) a normal estrogen level in a maternal urine sample. Twenty-six cases were classified without a functional hypothalamohypophysial system and seven had a functional hypothalamohypophysial system.

Birth weight was increased only in anencephalics with a functional hypothalamohypophysial system born to a mother with diabetes. The birth weight of anencephalics without a functional hypothalamohypophysial system was between the 10th and 25th percentiles. Polyhydramnios (more than 2 L of fluid) was present in 24 of 26 cases without a functional hypothalamohypophysial system and in only one of seven anencephalics with a functional HH system (the mother had diabetes). We suggested at that time that only anencephalics with a functional hypothalamohypophysial system are capable of swallowing. Because we did make some clinical observations of these cases, information is available on the natural history of anencephaly after birth. The Apgar score 5 minutes after birth was always <4 in anencephalics without a functional hypothalamohypophysial system, except in one case the Apgar score was >4 in an anencephalic with a functional hypothalamohypophysial system.

The anencephalics did not receive any intensive treatment. Of the 26 cases without a functional hypothalamohypophysial system, 12 newborns died within 1 hour, 7 died the next hour, and all died within 4 hours. Of the seven cases with a functional hypothalamohypophysial system, one newborn died within 4 hours, a second died within 24 hours, two died the second day, and three died the third day.

It seems that anencephalics are certainly not a ho-

6/1/20578

mogeneous group with regard to transplantation; furthermore we thought that such cases with a functional hypothalamohypophysial system did have pain reactions. In addition, endocrine disorders are present in such newborns. These changes may be of importance concerning the functional capacity of the donated organ. Certainly in anencephalics without a functional hypothalamohypophysial system the endocrine pancreas does not reach full maturation, which can cause problems when these glands are used for islet transplantation.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Study of internal structure of the human fetus in utero by echo-planar magnetic resonance imaging

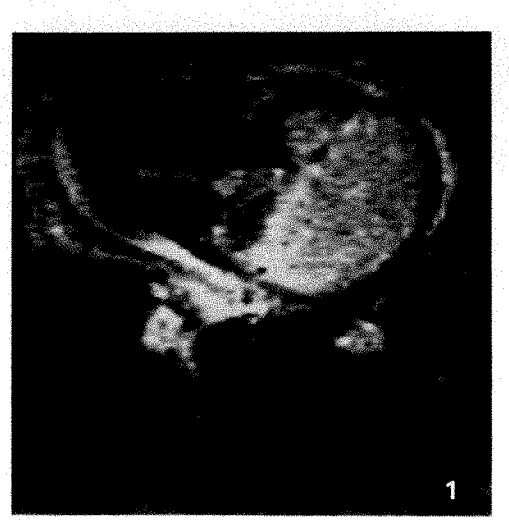
Ian R. Johnson, BSc, MB, BS, DM,[b] Michael K. Stehling, DrMed,[a] Andrew M. Blamire, BSc,[a] Ronald J. Coxon, BSc, PhD,[a] Alistair M. Howseman, BSc,[a] Barry Chapman, BSc, PhD,[a] Roger J. Ordidge, BSc, PhD,[a] Peter Mansfield, BSc, PhD,[a] Edwin M. Symonds, MD,[b] Brian S. Worthington, BSc, MB, BS, DMRD,[c] and Rex E. Coupland, MD, PhD, DSc[c]

Nottingham, England

The ultrafast echo-planar magnetic resonance imaging technology, developed and built in Nottingham, has been used to produce the first snapshot images of the human fetus in utero. The imager, operating at a proton resonance frequency of 22 MHz, produces transaxial views in 64 or 128 milliseconds. These images comprise either 64 × 128 or 128 × 128 pixels with an in-plane resolution of 3 × 3 mm^2. The slice thickness is 10 mm. Fetal scans of up to 32 contiguous slices are produced in a few minutes. These have been used to study the internal structure of the uterus and the fetus in a range of cases with gestations ranging from 26 weeks to term. Echo-planar imaging seems particularly suitable as an imaging modality since its high speed obviates image blurring arising from fetal motion. (AM J OBSTET GYNECOL 1990;163:601-7.)

Key words: Echo-planar imaging, snapshot magnetic resonance imaging, fetal scans in utero

Echo-planar imaging[1, 2] is a particular form of magnetic resonance imaging in which complete snapshot images are obtained in ≤128 milliseconds. It evolved from the principles of magnetic resonance imaging introduced by Mansfield and Grannell[3] in 1973. In this article is presented a series of images obtained from the human fetus in utero during the second and third trimesters of pregnancy with the echo-planar imaging technique. These pictures have been obtained from the first pregnant patients who underwent imaging with a unique home-built magnetic resonance machine. Preliminary reports of this work are given elsewhere.[4-7]



Methods and patients

All images were obtained with a 0.5 T superconductive magnet with the modulus-blipped echo-planar single-pulse technique,[8-11] a variant of the original echo-planar technique.[1] Full details of the application of this technique to imaging pregnant patients are described elsewhere.[12] Two-dimensional images were obtained in either 64 or 128 milliseconds after a single excitation of the spin system. A modulus Fourier transformation converted the raw data into the final magnetic resonance image. Resolution varied between 1.5 and 3 mm. In ultra-high-speed echo-planar imaging complete echo-planar images may be acquired, formed, and displayed in real time at up to 20 frames per second.[10] In the present work frame rates of 1 or 2 per second were used. Sixteen patients have had imaging done with this technique, at gestations varying from 21 weeks to term. All of the fetuses imaged so far have been from pregnancies deemed to be abnormal, with congenital abnormalities previously diagnosed on ultrasonography, suspected intrauterine growth retardation, or problems with the placental site. Fully informed and written consent was obtained from all patients. Permission for imaging of patients in the second and third trimesters of pregnancy in Nottingham has been obtained from the local committee on ethics. The imaging conditions used in this study were all well within the safety guidelines recommended by the National Radiological Protection Board.

Results

Fig. 1, *1*, shows a transverse section through the pelvis of a woman who was 38 weeks pregnant. The maternal spine is at the bottom of the picture and an oblique coronal section is shown through the fetal skull and brain. The slice is 10 mm thick. The fetus is outlined by a rim of white amniotic fluid. The bone of the fetal

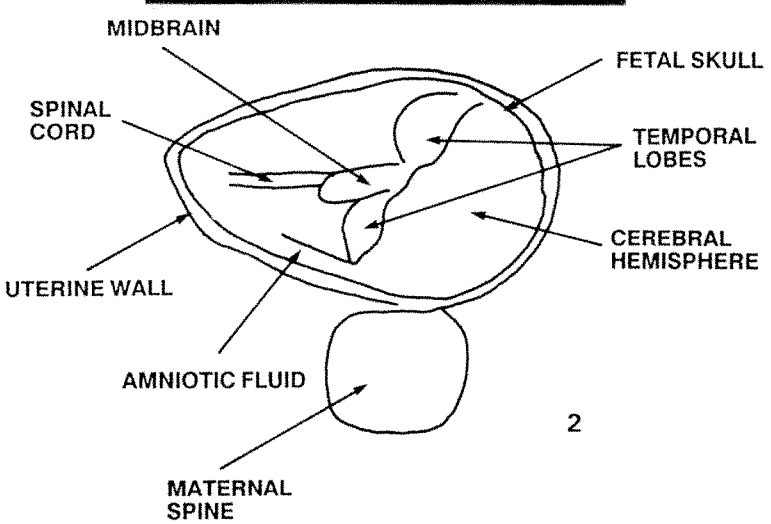

Fig. 1. 1, Echo-planar transectional snapshot through a 38-week fetal head. Image exposure time 128 milliseconds. Slice thickness 10 mm. In-plane resolution 3 × 3 mm^2 (13101). **2,** Annotated sketch showing salient features of **1**.

skull appears dark because of its low signal, but within this can be seen the fetal brain, which is homogeneous because of its lack of myelination. The cerebral hemispheres appear laterally on the right side of the uterus with the temporal lobes seen anteriorly and posteriorly in the midline. The midbrain, lower brain stem, and upper spinal cord are seen running away obliquely. The pons is shown particularly clearly. Fig. 1, *2*, is a sketch with salient features annotated.

Fig. 2, *1*, shows a transverse section through the pelvis of a pregnant patient at 40 weeks' gestation. The maternal spine, with a high signal from the cerebrospinal fluid, is shown in the lower part of the picture. The uterus and its contents occupy the upper part of the picture. The amniotic fluid has a high water content and consequently a high signal while an intermediate signal is seen from the rim of placenta lining the posterior aspect of the uterus. The fetus is facing to the right. A transverse section through part of the fetal brain is shown enclosed within the low signal of the fetal skull (see annotated sketch of Fig. 2, *2*). The cerebral hemispheres, the temporal lobes, and the brain stem can be seen clearly.

Fig. 3, *1* through *5*, shows five transverse images taken at intervals through the fetal chest in a 37-week pregnancy. The placenta is on the right lateral, posterior aspect. The fetus is on the left anterolateral aspect facing the placenta (see annotated sketch, Fig. 3, *6*). In each of the pictures the fetal spinal canal can be seen in the left anteriolateral aspect of the uterus and appears as a high signal representing the cerebrospinal fluid in the spinal canal. A dark circle anterior

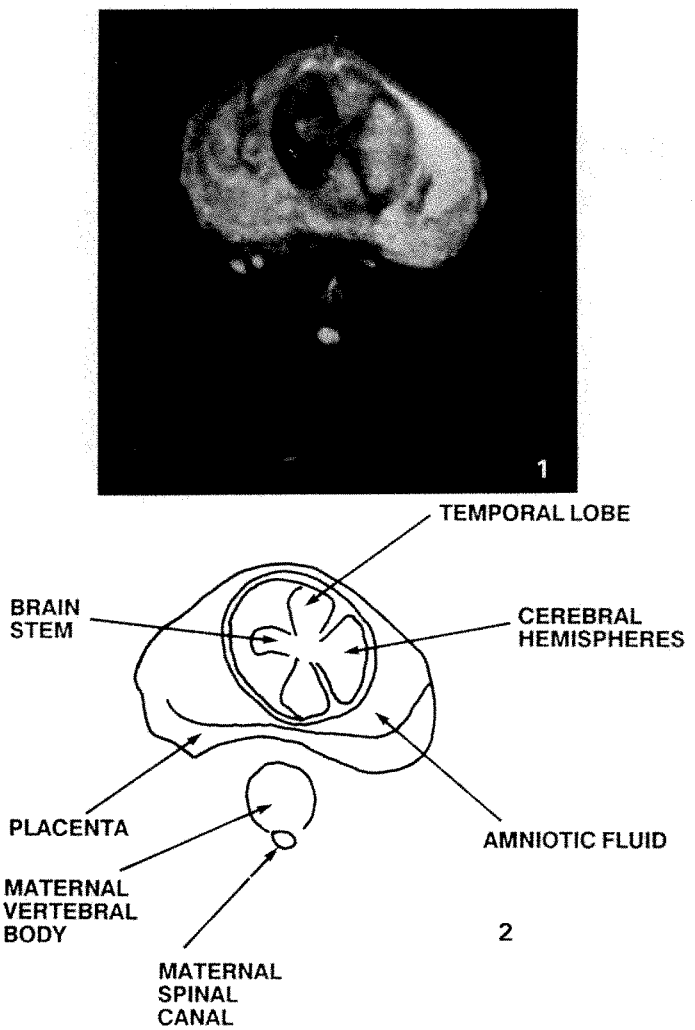

Fig. 2. 1, Transaxial snapshot image through uterus at 40 weeks' gestation. The imaging plane is through the fetal cerebral hemispheres. Imaging time 128 milliseconds. In-plane resolution 3 × 3 mm^2 (15501). **2,** Annotated sketch of **1** above, indicating major morphologic detail.

to it within the fetus, represents the fetal vertebral body. Within the fetus the lungs lie anteriorly to the spinal canal and vertebral body and on either side of the midline. The lungs appear as high-signal areas, because of the fluid that they contain, fanning out from the hilum to the periphery on each side. This series of pictures shows the lung fields from the lung apexes (Fig. 3, *1*), enlarging as slices are taken serially through the chest, until they disappear at the level of the diaphragm in Fig. 3, *5*. It is clear that when contiguous slices with a given thickness (10 mm) are taken through the fetal chest the fetal lung volumes can be measured. In some of the images, particularly Fig. 3, *4*, the internal structure representing the blood vessels is seen within the lung fields. The heart lies anteriorly in the fetus between the two lung fields, but the interal structure of this organ is not seen particularly well in this series of images. In Fig. 3, *5*, the transverse slice is taken through the diaphragm and part of the upper abdomen. The area of high signal in the left of the fetus represents the uppermost part of the stomach. In Fig. 3, *3*, *4*, and *5*, the placenta is particularly well seen on the right lateral aspect of the uterus; considerable heterogeneity is seen, with the dark circular areas representing blood flow within this organ.

Fig. 4 shows two pictures of a series obtained from a 26-week fetus. The fetal heart is depicted in the middle of each picture with the lung fields to either side. In Fig. 4, *1*, the fetus is facing the maternal spine and all four cavities of the heart are shown as low-signal areas. The walls of the heart can be seen clearly, as can the intraventricular septum. The atria and ventricles

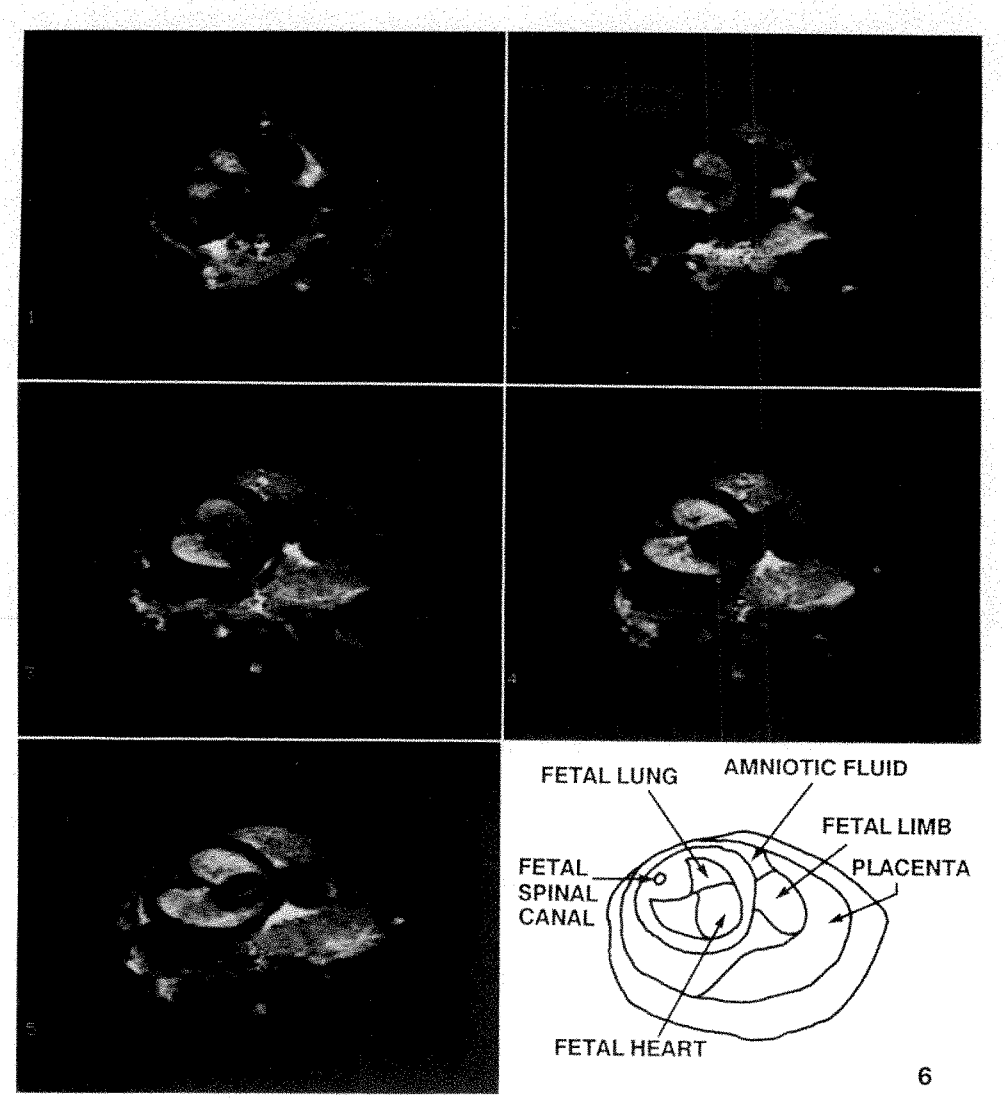

Fig. 3. 1 to **5,** Five contiguous transections through a fetal chest at 37 weeks' gestation. Snapshot exposure time 64 milliseconds. In-plane resolution 3 × 3 mm² (13201). **6,** Diagram illustrating main morphologic details of images **1** through **5**.

are demonstrated and the tricuspid and mitral valves can be distinguished. The low-signal areas in all four chambers are caused by the movement of the blood. For example, in Fig. 4, *2*, taken at a different stage of the cardiac cycle, although blood is still moving rapidly in the ventricles in systole, the flow is clearly more sluggish in the atria, yielding a high-signal intensity.

Fig. 5 shows three transverse slices taken through the abdomen of a fetus within the uterus of a patient who was 36 weeks pregnant. The maternal spine lies at the bottom of the picture with the uterus occupying the upper portion of each picture. The placenta lies laterally on the left with the fetus shown anterolaterally on the right facing the placenta. Considerable heterogeneity can be seen representing blood flow within the placenta on each of the pictures. The placental and fetal boundaries are outlined by the starkly white high signal of the amniotic fluid. The fetal abdomen is outlined by a low-signal ring that mainly represents subcutaneous fat. This has been deliberately suppressed by chemical selection of the water signal only.[13] In Fig. 5, *1*, the fetal spinal canal can be seen as a high-signal area posteriorly within the fetus. The vertebral body is a low-signal circular area immediately anterior to the canal, with the aorta and inferior vena cava immediately anterior to it. To either side of these vessels and the vertebral body, the upper part of the kidneys can be seen. The anterior part of the fetal abdomen is mainly occupied by the fetal liver, although some fluid can be seen in the first part of the duodenum, illustrated by the high-signal area. A loop of cord is seen within the amniotic fluid. In Fig. 5, *2*, the slice is taken

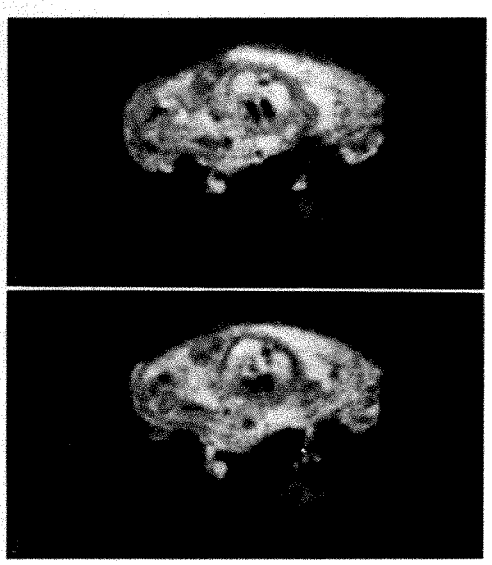

Fig. 4. Snapshot echo-planar imaging transections through mediastinum of fetus at 26 weeks' gestation. **1,** Four-chamber view through heart (dark region) in atrial and ventricular systole. **2,** Later in atrial diastole and ventricular systole. Atria appear bright because of slow flow, whereas ventricles appear dark because of high blood velocity. Imaging time 64 milliseconds. In-plane resolution 3 × 3 mm^2 (13001).

Fig. 5. Three snapshot echo-planar imaging transections at different levels in fetal abdomen. **1,** Fetal liver, **2,** Fetal kidneys. **3,** Fetal bowel and thighs. Imaging time 128 milliseconds. In-plane resolution 3 × 3 mm^2 (13201).

further down the fetal trunk. As before, the spinal canal can be seen posteriorly in the fetus with the vertebral body, the aorta, and the inferior vena cava anterior to it. To either side of these structures the central portions of the kidneys are clearly seen, particularly in the left kidney; also the renal pelvis and vessels coming from the kidney can easily be resolved. Fluid can be seen in the first part of the fetal small bowel, but the majority of the anterior abdomen is occupied by the fetal liver on the right and loops of bowel on the left. In Fig. 5, *3*, the slice has been taken further down the trunk. The lower poles of the kidneys can still be seen but the remainder of the abdomen is filled with loops of bowel. The fetal thighs have appeared within the amniotic fluid, with the dark central areas representing cross sections of the femur surrounded by the higher signal of the muscle bundles. Fat surrounds these structures, and because the fat signal is suppressed, they are outlined well against the high-signal amniotic fluid.

Fig. 6 is the final sequence taken from the same patient as seen in Fig. 5. These pictures are shown at 10 mm intervals through the fetal pelvis. In Fig. 6, *1*, the pelvis and right leg are outlined within the high-signal amniotic fluid. The structure of the femur can be seen clearly, including the head and neck of the bone, showing as a dark, low-signal area within the fetal thigh. Growing bone within the fetal knee shows as a high-signal area in both the femur and the upper tibia. Muscle groups can be seen within the fetal leg and in the gluteal regions. In Fig. 6, *2*, the joint space in the right knee is seen particularly clearly as a low-signal area between the femur and the tibia. The upper part of the bladder is beginning to appear as a high-signal area within the pelvis. A dark rim of low-signal fat is shown in the fetal buttock. In Fig. 6, *3*, the left leg is seen clearly. The fetal bladder is shown as a high-signal area within the pelvis, demonstrating the urine within it. The low-signal buttock fat is still present, but, in addition, the low signal of the sacral and iliac parts of the pelvis is seen posteriorly and to either side within the fetal pelvis.

Comment

Conventional magnetic resonance imaging of fetuses in the second and third trimesters of pregnancy has been performed for several years with a commercial machine that uses slower imaging techniques.[14, 15] However, because of fetal movement and the relatively long imaging times, blurring of the pictures occurs. Although fetal detail has been displayed occasionally, re-

Fig. 6. Three echo-planar imaging snapshots showing coronal views of fetal limbs and pelvis. **1** and **2,** Right femur, tibia, and pelvic girdle. **3,** Left leg, pelvis, and bladder. (Note maternal kidneys and spine.) Imaging time 64 milliseconds. In-plane resolution 3 × 3 mm^2 (13301).

liable measurements are not possible. As the fetus becomes larger, with increasing gestation, more detail becomes apparent. However, the internal structure of the fetus is seen very poorly and the standard nuclear magnetic resonance techniques provide relatively disappointing results apart from location of the placenta.[15]

Echo-planar imaging is a major advance over conventional magnetic resonance imaging. In this article some of the first motion-free magnetic resonance images of the human fetus in utero are shown. The images acquired with echo-planar techniques give a snapshot image in a fraction of a second, and consequently motion of the fetus is frozen in time. Different fast magnetic resonance imaging techniques are being developed by others,[17, 18] but these methods are currently unable to compete on speed.

The internal structure of many fetal organs is seen clearly, and as this experimental technique improves, there is considerable potential for the study of the internal structure of the organs in utero. Accurate measurements can be made of fetal organ volumes, for example, lung and liver volumes, which may be of considerable clinical importance when premature delivery is contemplated or the fetus is thought to be growth-retarded. Echo-planar imaging has already beeen used to measure lung volume in infants.[16] The multiparametric magnetic resonance image with specific pulse sequences allows a high level of tissue characterization, which makes this technique a useful adjunct to ultrasonography. In particular the differentiation between fats and other structures in the fetus will be useful, especially in studying development of the growth-retarded fetus.

Current echo-planar images have a slightly lower spatial resolution than ultrasonography, but tissue contrast and specificity are higher and the pictures are far easier to interpret than those obtained with ultrasonography. We believe that echo-planar magnetic resonance imaging has considerable potential for intrauterine assessment of the human fetus, in both normal and abnormal pregnancies.

We thank the Medical Research Council and the Department of Health for major support of the echo-planar imaging program. We are also grateful to the British Heart Foundation for financial contributions to our data acquisition and processing hardware. M. K. S. and A. M. B. thank the Deutsche Forschungsgemeinschaft and the Science and Engineering Research Council respectively for research studentships.

Hyperkalemia after irradiation of packed red blood cells: Possible effects with intravascular fetal transfusion

James A. Thorp, MD,[a] Fred V. Plapp, MD, PhD,[b] Gary R. Cohen, MD,[a] John D. Yeast, MD,[a] Richard T. O'Kell, MD,[b] and Stephanie Stephenson, RN[a]

Kansas City, Missouri

Plasma potassium, calcium, and albumin concentrations in irradiated blood, and in fetal blood before and after transfusion, were measured. Dangerously high plasma potassium levels were observed in some units of irradiated packed red blood cells (range, 13.9 to 66.5 mEq/L; mean, 44.7 mEq/L) and could be one possible explanation for the high incidence of fetal arrhythmia associated with fetal intravascular transfusion. There are many factors operative in the preparation of irradiated packed red blood cells that may predispose to high potassium levels: the age of the red blood cells, the number of procedures used to concentrate the blood, the duration of time elapsed from concentration, the duration of time elapsed from irradiation, and the hematocrit. Use of fresh blood, avoidance of multiple packing procedures, limiting the hematocrit in the donor unit to ≤80%, and minimizing the time between concentration, irradiation and transfusion may minimize the potassium levels, and therefore making an additional washing procedure unnecessary. (Am J Obstet Gynecol 1990;163:607-9.)

Key words: Hyperkalemia, fetal intravascular transfusion, irradiation of packed red blood cells

Irradiation of blood before transfusion of the fetus and neonate is important because it effectively prevents graft versus host disease. Recent reports suggest that irradiation results in hyperkalemia in the donor plasma.[1-4] Ramirez et al.[1] found plasma potassium levels to be 53 mEq/L after irradiation and 4 days of storage, compared with a control value of 17 mEq/L. Two other studies[2,3] reported similar elevations of potassium after irradiation and found that potassium levels could be significantly reduced by manual washing procedures. These elevated potassium levels may cause dangerously high plasma concentrations in the fetus or neonate.[3,4] A 24-week fetus weighing 600 gm has a circulating fetoplacental blood volume of approximately 96 ml. Blood transfusions in excess of 50 ml/kg fetal weight are being performed by us and others. If such a fetus (hematocrit = 20% and plasma potassium = 3.5 mEq/L) receives 30 ml of transfused blood (hematocrit = 80% and plasma potassium = 50 mEq/L), the potassium bolus into the central vein exceeds the total plasma potassium of the entire fetoplacental unit. This massive potassium bolus injected into a central vein of an already compromised fetus may account for the high frequency of fetal arrhythmia associated with intravascular fetal transfusions.[3] Fetal arrhythmias associated with intravascular transfusion may be lethal.[3] Other factors including the temperature of transfused blood, volume transfused, citrate concentrations, and calcium levels may also predispose to fetal arrhythmia during intravascular transfusion.

Table I. Potassium, calcium, and albumin in donor blood and in fetal blood before and after transfusion

	Mean ± SD	*N*
Potassium in donated blood (mEq/L)	44.7 ± 17.9	8
Pretransfusion fetal potassium (mEq/L)	3.3 ± 0.3	4
Posttransfusion fetal potassium (mEq/L)	4.1 ± 0.7*	6
Calcium in donated blood (mEq/L)	8.2 ± 0.8	5
Pretransfusion fetal calcium (mEq/L)	8.9 ± 0.1	3
Posttransfusion fetal calcium (mEq/L)	9.1 ± 0.3	3
Albumin in donated blood (gm/dl)	3.0 ± 0.2	5
Pretransfusion fetal albumin (gm/dl)	2.3 ± 0.2	3
Posttransfusion fetal albumin (gm/dl)	2.0 ± 0.8	3

*Significantly increased from pretransfusion value, $p < 0.05$ by t test.

Table II. Factors predicting plasma potassium levels in units of irradiated packed red blood cells ($n = 8$)

	Mean ± SD	*t Value*	*p Value**
Age of unit before radiation (hr)	93.0 ± 27.0	0.50	0.64
Time between radiation and transfusion (hr)	12.6 ± 6.7	2.50	0.06
Hematocrit of unit (%)	77.0 ± 8.8	3.00	0.04

*The p value is determined by multivariate regression analysis with plasma potassium in the irradiated packed red blood cells used as the dependent variable and each of the three factors used as the independent variables.

Table III. Effect of a single concentrating procedure versus two concentrating procedures on plasma potassium of fresh blood

No. of procedures	*n*	*Hematocrit (%)*	*Potassium (mEq/L)*
1	9	74.7	4.0
2	4	91.3*	5.5*

*These values are significantly increased when compared with the values obtained after only one concentrating procedure ($p < 0.001$ by t test).

Methods

Recently we measured potassium, calcium, and albumin concentrations in irradiated blood and in fetal blood before and after transfusion (Table I). Potassium levels in units of irradiated packed red blood cells ranged from 13.9 to 66.5 mEq/L (mean, 44.7 mEq/L; SD = 17.9 mEq/L; $n = 8$). Large boluses of intravenous potassium in the fetus do not appear to cause a sustained increase in serum potassium, presumably because of tissue equilibration, renal excretion, and placental transfer. We have observed a fetal potassium increase from 3.2 mEq/L before transfusion to 5.3 mEq/L after transfusion, without resultant fetal arrhythmia. In another fetus we transfused 54 ml of blood with a serum potassium of 66.5 mEq/L to a 1550 gm fetus without evidence of arrhythmia. The equivalent volume of hyperkalemic solution injected rapidly into the central vein of an adult would be very dangerous. We have seen four transient fetal arrhythmias during or after 42 intravascular transfusions. Since we began monitoring fetal potassium levels, only one of seven transfusions was associated with a fetal arrhythmia. This one instance of transient bradycardia occurred immediately after transfusion of 75 ml of donor blood with a plasma potassium of 58 mEq/L to an 800 gm fetus.

Results

Multivariate regression analysis was performed to determine which of the following factors (age of the unit of blood before irradiation, hematocrit of the unit of packed red blood cells, and the time between irradiation of blood and transfusion) correlated best with the plasma potassium of the donor blood. Both the hematocrit of the unit of packed red blood cells and the duration of time between irradiation and transfusion correlated best (Table II). The three highest plasma potassium levels (66.5, 65.3, and 58.0 mEq/L) were associated with the three highest hematocrits (86%, 84%, and 84%, respectively). The lowest plasma potassium in the donor blood (13.9 mEq/L) was observed when the duration of time from irradiation to transfusion was only 3 hours. However, in one unit of blood we observed only a minimal rise in potassium, from 36 mEq/L 2 hours after irradiation to only 44.3 mEq/L 24 hours after irradiation. Therefore there appears to be other factors involved with the rise in potassium levels.

Because the variance in the plasma potassium of the donated blood could not be explained entirely by the hematocrit of the donor blood or the time elapsed after irradiation, we sought other explanations. We found that the regional blood center had concentrated some units of blood a second time to achieve a higher he-

matocrit. To further clarify this issue we studied nine additional units of fresh blood (≤5 days of age), five of which were centrifuged only once, and four of which were centrifuged twice and had plasma removed after each centrifugation (Table III). The hematocrit and potassium levels were significantly elevated ($p < 0.001$) after the second centrifugation. This probably occurred because the highly concentrated units had additional plasma removed. There was less plasma available for distribution of the potassium leaking out of the irradiated red blood cells. In addition, the removal of more anticoagulant-preservative solution resulted in less adenosine and glucose to support sodium-potassium adenosine triphosphatase. Inhibition of this enzyme would further accentuate potassium leakage.

Comment

There appear to be many factors operative in the preparation of irradiated packed red blood cells that may predispose to high potassium levels: the age of the red blood cells, the number of procedures used to concentrate the blood, the duration of time elapsed from concentration, the duration of time elapsed from irradiation, and the hematocrit. We conclude that each of these factors may contribute to cause a slow potassium leak in the red blood cell membrane, therefore causing a rising plasma potassium. Manual washing of irradiated packed red blood cells with saline solution significantly reduces the donor plasma potassium. This procedure is technically cumbersome and adds further time delay and expense. Use of fresh blood, avoidance of multiple packing procedures, and minimizing the time between concentration, irradiation, and transfusion may keep the potassium levels low, therefore making an additional washing procedure unnecessary. Further study is necessary to determine how much potassium can be safely administered during intravascular transfusion, and to determine if washing techniques are necessary.

Lymphocyte proliferative response to fertilization antigen in patients with antisperm antibodies

Rajesh K. Naz, PhD,[a] Anu Chaudhry, MD,[b] and Steven S. Witkin, PhD[b]

Bronx and New York, New York

The fertilization antigen, immunopurified from human testes, activated lymphocytes from three of the six men and women with antisperm antibodies. Lymphocytes from none of the six men and women without antibodies were activated with fertilization antigen. Another sperm surface antigen, the germ cell antigen, immunopurified from murine testes, did not activate lymphocytes from any of the individuals with or without antisperm antibodies. These results indicate that the men and women with antisperm antibodies are sensitized against fertilization antigen and not germ cell antigen. These results reinforce our previous findings on the involvement of fertilization antigen in immunoinfertility in humans. (AM J OBSTET GYNECOL 1990;163:610-3.)

Key words: Antisperm antibodies, sperm antigens, cell-mediated immune responses, immunocontraception

Cell-mediated immune responses are readily induced to foreign cellular and viral antigens.[1, 2] Studies regarding the occurrence of cell-mediated immune responses to sperm, however, have claimed conflicting results. There are reports indicating the inability,[3] or conversely, ability[4, 5] of sperm (allogeneic or autologous) to activate lymphocytes. These conflicting data may possibly be a result of the presence of defective or dead sperm combined with motile sperm in the activating preparation, failure to remove somatic cells from semen before analysis, and the use of nonhuman sera.[6] One approach to evaluate whether sperm induce lymphocyte proliferation is to use sperm-specific antigens.

We have isolated and characterized a sperm-specific glycoprotein, the fertilization antigen from human and murine male germ cell plasma membranes.[7] The tissue-specific but species-cross-reactive monoclonal antibody to fertilization antigen inhibits human sperm penetration of zona-free hamster ova and blocks fertilization of murine oocytes by murine sperm.[8] The fertilization antigen is also involved in involuntary immunoinfertility in humans.[9, 10]

We have isolated and characterized another sperm antigen, the germ-cell antigen, from male germ cell plasma membranes.[11] The antibodies to germ cell antigen cause postfertilization reduction of fertility in rabbits and mice by inhibiting early embryonic development.[12] The antibodies to germ cell antigen bind to human sperm but do not inhibit penetration of zona-free hamster eggs. It has not been tested whether the immunoinfertile patients have antibodies to germ cell antigen.

The purpose of this study was to investigate whether these two well-defined sperm antigens (fertilization antigen purified from human testes and germ cell antigen purified from murine testes) could activate lymphocytes from immunoinfertile patients. In general, these studies were directed at exploration of the cell-mediated immune responses to sperm antigens and investigation of the involvement of fertilization antigen in immunoinfertility in humans.

Material and methods

Antigens

Fertilization antigen. Fertilization antigen was purified from lithium diiodosalicylate–solubilized human testes by immunoaffinity chromatography involving monoclonal antibodies that inhibit fertilization.[7, 8] Two-dimensional polyacrylamide gel electrophoresis, high-performance liquid chromatography, density gradient ultracentrifugation, and amino acid analysis indicated that purified antigenic molecule is composed of a monomer of 23,000 d and/or a dimer of 47,000 to 50,000 d.[9] Each batch of fertilization antigen was tested for its homogeneity. Only those batches that showed specific bands of 23,000 d and/or 47,000 to 50,000 d in sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) were used in this study. Fertilization antigen primarily showed its dimeric form.

Germ cell antigen. Germ cell antigen was purified from lithium diiodosalicylate–solubilized murine testes with immunoaffinity chromatography involving monoclonal antibodies that cause postfertilization inhibition of fertility.[11, 12] After washing the unbound proteins with phosphate buffer (0.1 mol/L) at pH 8, the bound proteins were stepwise eluted with glycine–hydrochloric acid buffer (0.1 mol/L) first at pH 4 and then at pH 2.8. The peak eluted at pH 2.8 was neutralized with 1 mol/L potassium phosphate, concentrated, dialyzed against lithium chloride and then against phosphate-buffered saline solution (0.1 mol/L, pH 7.4), and frozen (−70° C) until further use. Only those batches that showed specific band of 63,000 d in nonreduced SDS-PAGE were used.

Polyacrylamide gel electrophoresis. The slab SDS-PAGE containing 10% gel was run under nonreducing conditions according to the method of Laemmli.[13] The gels were stained with Coomassie blue R, silver nitrate, or both stains.

Subjects. Peripheral blood mononuclear cells and sera were collected from six infertile adults (four men and two women) who had positive cultures for antisperm antibodies. Cultures from all subjects were negative for bacteria in the semen or cervix. Six fertile adults (one man and five women) without antisperm antibodies in the sera were also included as controls.

Sperm antibody assay. The presence of antibodies in sera was determined by the indirect Immunobead binding assay with isotype-specific reagents.[14] A positive test was defined as binding to at least 40% of the motile sperm.

Lymphocyte proliferative assay. Peripheral blood mononuclear cells were isolated from heparinized blood by Ficoll-hypaque gradient centrifugation.[6] Washed cells were incubated in wells of a microtiter plate containing, in a final volume of 0.2 ml, 2×10^5 peripheral blood mononuclear cells, 10% fetal bovine serum in RPMI 1640 medium with 25 mmol/L Hepes buffer, and L-glutamine supplemented with penicillin (100 U/ml), streptomycin (100 μg/ml), and kanamycin (100 μg/ml) and containing 1.2 to 2.4 μg of the antigen protein (fertilization antigen or germ cell antigen). After 6 days of incubation at 37° C, the cultures were pulsed with ^{3}H-thymidine (0.2 μCi per well) and harvested 18 hours later. Each sample was analyzed in triplicate for isotope incorporation into peripheral blood mononuclear cells. Blank samples consisting of cultures without the test antigens and positive controls consisting of cultures incubated with concanavalin A instead of sperm antigens were always analyzed in parallel with the test samples. Results were converted to a stimulation index according to the following formula: Stimulation index = Counts per minute in presence of antigen/Counts per minute in absence of antigen. A stimulation index >2 was considered evidence of specific stimulation.

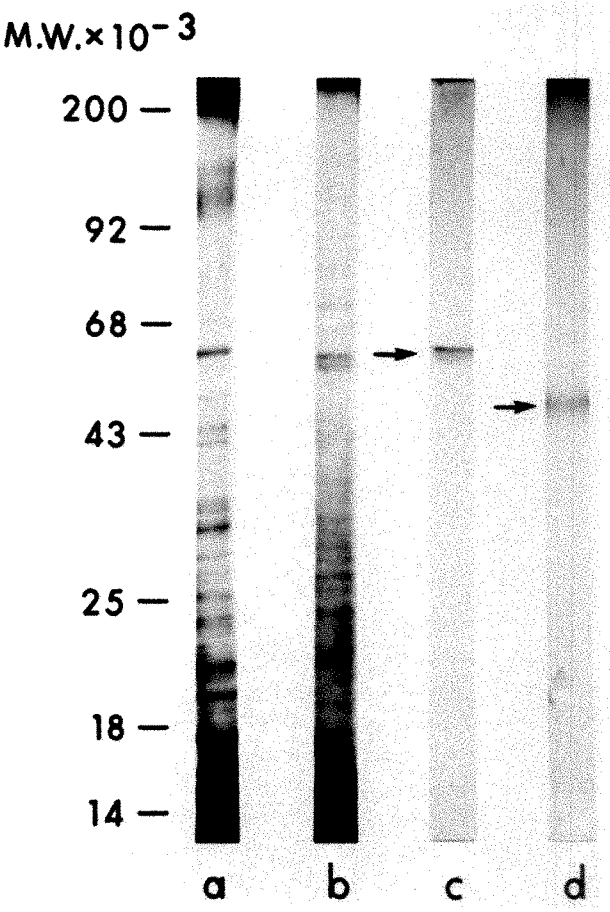

Fig. 1. The nonreduced SDS-PAGE pattern of the antigenic preparations stained with silver nitrate. Fertilization antigen showed a single band (↑) of 47,000 to 50,000 d (dimer) *(lane d)*. Germ cell antigen showed a single band (↑) of 63,000 d *(lane c)*. The lithium diiodosalicylate–solubilized human testes preparation *(lane a)* and lithium diiodosalicylate–solubilized murine testes preparation *(lane b)*, from which fertilization antigen and germ cell antigen, respectively, were purified, showed numerous bands of various molecular identities. The gels were calibrated with prestained molecular weight markers.

Statistical analysis. Differences between the stimulation indices of the control and antibody-positive lymphocytes were evaluated with unpaired Student's *t* test.

Results

The immunoaffinity-purified fertilization antigen showed a single band of 47,000 to 50,000 d (dimeric form) (Fig. 1, lane d), whereas germ cell antigen demonstrated a single band of 63,000 d (Fig. 1, lane c) in nonreduced SDS-PAGE. The lithium diiodosalicylate–solubilized human testes (Fig. 1, lane a) and lithium diiodosalicylate–solubilized murine testes (Fig. 1, lane b) demonstrated numerous bands of various molecular identities.

Table I. Lymphocyte proliferative response to sperm antigens

	Sex	Sperm antibodies	Stimulation index	
			Human fertilization antigen	*Mouse germ cell antigen*
Control No.				
1	F	—	0.9	0.2
2	F	—	0.6	0.4
3	F	—	1.0	1.0
4	F	—	0.4	0.2
5	F	—	0.6	0.4
6	M	—	0.7	—
Patient No.				
1	F	IgG	2.1	0.4
2	F	IgG	1.3	0.2
3	M	IgG, IgA	1.4	0.8
4	M	IgG	4.3	0.9
5	M	IgG	3.6	0.8
6	M	IgG	1.4	0.9

Peripheral blood mononuclear cells (2×10^5 per well) were incubated in RPMI 1640 medium containing 10% fetal bovine serum with or without 1.2 to 2.4 μg of the test antigen. Cultures were pulsed with ^{3}H-thymidine after 6 days and harvested 18 hours later. Positive reactions (stimulation index >2) have been underscored.

When investigated for their ability to activate lymphocytes, the purified antigens (fertilization antigen and germ cell antigen) yielded different results (Table I). Lymphocytes from none of the six fertile controls (men and women), who had no antisperm antibodies in sera, were activated with either antigen. In contrast, lymphocytes from three of the six patients with antisperm antibodies (men and women) were activated (>2, stimulation index) with fertilization antigen to various degrees. The remaining three showed some stimulation; however, the stimulation index was <2. Overall, the antibody-positive group showed a significantly ($p < 0.001$) higher stimulation index (mean ± SD, 2.35 ± 1.29) as compared with the antibody-negative group (mean ± SD, 0.70 ± 0.22). The germ cell antigen did not stimulate lymphocytes from either infertile patients with antibodies or fertile controls without antibodies (Table I). Overall, the stimulation index of the antibody-positive group (mean ± SD, 0.67 ± 0.29) was statistically insignificant compared with the antibody-negative group (mean ± SD, 0.44 ± 0.33). Lymphocytes from all the infertile patients with antibodies and fertile controls without antibodies responded equally well (stimulation index >2) to concanavalin A; the difference between the two populations was statistically insignificant.

Comment

Our data indicate that lymphocytes from some of the infertile patients with antisperm antibodies are sensitized to fertilization antigen. Lymphocytes from three of the six patients were activated with fertilization antigen as demonstrated by a stimulation index >2. Lymphocytes from both men and women with antisperm antibodies showed activation indicating the autosensitization and isosensitization of lymphocytes with this sperm antigen. Lymphocytes from none of the six fertile controls were activated with fertilization antigen, indicating that they were not sensitized against fertilization antigen. These data agree with our previous findings that fertilization antigen showed a strong reactivity with sera from immunoinfertile patients and did not react with sera from fertile controls.[9, 10]

In contrast to fertilization antigen, a second sperm antigen, germ cell antigen, did not activate lymphocytes from infertile men and women with antisperm antibodies, indicating that they were not sensitized to germ cell antigen. Similar results were obtained with lymphocytes from controls without sperm antibodies. Although germ cell antigen used in this study was isolated from murine testes, antibodies to germ cell antigen cross react with human sperm antigen. These results indicate that infertile subjects with antisperm antibodies may not be sensitized to all the sperm antigens.

The lymphocytes used in this study were a mixture of T cells and B cells. In another study in mice, we have shown that T lymphocytes presensitized to fertilization antigen in vivo secrete soluble factors on activation with this antigen in vitro.[15] These soluble mediators activated macrophages, and significantly inhibited sperm motility and embryonic development. Further analysis of the soluble factors indicated high levels of interferon-γ and tumor necrosis factor in addition to other undefined factors. These studies suggest that sperm antigens such as fertilization antigen may induce cell-mediated immune factors that may have detrimental effects on sperm motility and preimplantation embryonic development. Possible mechanisms of early-stage miscarriage related to a woman's sensitization to sperm have recently been proposed.[16, 17]

In conclusion, our data indicate that lymphocytes from infertile men and women with antisperm antibodies are sensitized to fertilization antigen and not to germ cell antigen. This further implicates the involvement of fertilization antigen in immunoinfertility in humans. This is the first report indicating the sensitization of lymphocytes from infertile patients against a purified sperm antigen.

We thank Karen Wayns-Lee for technical assistance.

Effects on bone of surgical menopause and estrogen therapy with or without progesterone replacement in cynomolgus monkeys

Manuel J. Jayo, DVM, PhD,[a] David S. Weaver, PhD,[a, b] Michael R. Adams, DVM,[a] and Samuel E. Rankin, BA[a]

Winston-Salem, North Carolina

The influence of estrogen replacement therapy on bone loss of surgically postmenopausal cynomolgus macaques was evaluated histomorphometrically using the first (L-1) lumbar vertebra and ex vivo dual photon absorptiometry of the third (L-3) lumbar vertebra. The animals were a subgroup of a larger study on the effects of estrogen replacement therapy on diet-induced coronary artery atherosclerosis. The three experimental conditions were as follows: untreated females with oophorectomy, females with oophorectomy treated with continuous estrogen replacement therapy plus cyclic progesterone, and females with oophorectomy treated with estrogen replacement therapy. Bone mineral density (grams per square centimeter) of L-3, when covaried for body mass index (body mass index, body weight/(trunk length/100)^2), was significantly lower for the oophorectomy group compared with the group treated by estrogen replacement therapy plus progesterone and estrogen replacement therapy groups ($p = 0.018$). When covaried for body mass index, trabecular bone volume percentage of a midsagittal section of L-1 was not significantly different between groups, but the adjusted mean was greatest in the estrogen replacement therapy plus progesterone group, followed closely by the estrogen replacement therapy group, and was least in the oophorectomy group. When covaried for body mass index, trabecular plate number was significantly lower ($p = 0.022$) and mean trabecular plate separation was significantly higher ($p = 0.033$) in the oophorectomy group. Thus both estrogen replacement therapy and estrogen replacement therapy plus progesterone provided overall protection against surgical menopause–associated bone mass loss. Cynomolgus macaques are an extremely useful animal model for estrogen replacement therapy use in prevention of postmenopausal bone loss. (Am J Obstet Gynecol 1990;193:614-8.)

Key words: Monkeys, oophorectomy, 17β-estradiol, progesterone, bone histomorphometry, dual photon absorptiometry

Osteoporosis is a common disease in which bone tissue, bone mass, or both is reduced, increasing the risk of fractures.[1, 2] Osteoporosis affects as many as 15 to 20 million individuals in the United States and leads to an estimated 1.3 million bone fractures a year.[2] The annual direct costs of osteoporosis incurred by American women aged 45 years and older in 1986 are estimated at $5.2 billion dollars.[1] Women are at greater risk of developing osteoporosis than men, and women's risk increases if they are naturally or surgically postmenopausal, probably as a result of the well-known accelerated, but transient, bone loss phase resulting from estrogen deficiency. The osteoporosis risk for women increases further if they are small, slender or nonathletic, if they are white or Asiatic, if they smoke, or drink excessive amounts of coffee or alcohol.[1, 2] Some of the osteoporosis risk factors are also associated with increased risk of coronary heart disease or death.[3] Consequently, appropriate treatment for osteoporosis should focus both on prevention or slowing the loss of bone mass and decreasing the risk of coronary heart disease. We concur with Hillner et al.[4] that any treatment regimen for postmenopausal osteoporosis that omits its cardiovascular consequences markedly underestimates the potential gains from therapy.

In 1984 the National Institutes of Health Consensus Conference on Osteoporosis recommended estrogen replacement therapy, increased consumption of calcium, and weight-bearing exercise for postmenopausal

6/1/21799

women.[2] Conversely, estrogen replacement therapy supplemented with progesterone currently is a widely recommended form of therapy.[2, 5] There is convincing evidence that progesterone supplementation is associated with a reduction in endometrial cancer risk in women receiving estrogen replacement therapy.[2, 5] Progesterone supplementation also may augment the beneficial effects of estrogens in providing protection against osteoporosis.[5] Other forms of therapy that often are directed at a particular event in the bone remodeling cycle include oral calcitriol, intranasal calcitonin, and fluoride therapy.[2] However, only therapies that include estrogen in their regimen seem to provide multisystemic benefits. Estrogen replacement therapy is effective in prevention and treatment of osteoporosis,[2] and in reducing the risk of coronary heart disease.[5]

Transdermal or subdermal 17β-estradiol (via implants) has been recommended as a way to provide adequate estrogen replacement therapy[6, 7] because it results in serum estrogen patterns typical of the early follicular phase of the menstrual cycle (estradiol/estrone ratio of approximately 1.0[8]) and because it prevents the hepatic first-pass presentation of estrogen that may be associated with perturbation of lipoprotein metabolism and coagulation.[8] We report the results of an experiment designed to study the benefits of estrogen replacement therapy with or without cyclic progesterone in the prevention of trabecular bone loss. Effects on coronary artery atherosclerosis are reported elsewhere.[6] This study should provide the basis for further studies of therapeutic regimens that would concurrently benefit the skeletal and cardiovascular systems.

Material and methods

Animals. The animals were subjects in a large experiment designed to study the inhibition of diet-induced coronary artery atherosclerosis by estrogen replacement therapy or estrogen replacement therapy plus progesterone in surgically postmenopausal cynomolgus monkeys *(Macaca fascicularis)*.[6] Thirty-nine randomly chosen animals were used for the bone studies. These feral animals were imported from Jakarta, Indonesia (Hazelton Research Products, Denver, Pa.). Cynomolgus macaques have been established as a model of postmenopausal or postoophorectomy bone loss[9-11] and are extremely useful in studies of reproductive hormone influences on coronary artery atherosclerosis.[6, 12, 13]

Experimental design and procedures. The animals were kept in social groups consisting of four or five females in indoor-outdoor pens measuring 2.0 × 3.2 × 2.5 m. The animals had water ad libitum and for 30 months were fed a moderately atherogenic semipurified diet that contained 2.5 IU of vitamin D_3 per gram of diet with a 1.17 calcium to phosphorus ratio (591 mg of calcium and 503 mg of phosphorus per 100 gm of food). The vitamin D_3 content and calcium and phosphorus ratio of the diet were appropriate for this group of young adult female macaques. The animals had bilateral oophorectomy 4 months after initiation of the diet regimen. Guidelines established by our institutional Animal Care and Use Committee, state and federal laws, and standards of the Department of Health and Human Services were followed throughout the experiment. The animals were randomly assigned to one of three experimental groups: *group 1*—untreated females, that had oophorectomy (n = 12); *group 2*—females that had oophorectomy that were treated with estrogen (1,3,5(10)-estratrien-3,17β-diol, Steraloids, Inc., Wilton, N.H.) plus cyclic progesterone (4-pregnene-3,20-dione, Steraloids, Inc.) replacement therapy (n = 15); and *group 3*—females that had oophorectomy and were treated with estrogen replacement (n = 12). The hormones were administered beginning 1 month after oophorectomy via subcutaneously implanted silicone rubber tubing. The estrogen implants had an inner diameter of 0.335 cm and an outer diameter of 0.465 cm, were 3.0 cm in length, and were filled with 17β-estradiol. The estrogen implant remained in the animals for the entire 25-month treatment period. During alternating 28-day periods, the animals in the estrogen plus progesterone group received a second implant (3.5 cm long) filled with progesterone.[6] Although this combination did not mimic the normal menstrual cycle, it provided for midfollicular phase estradiol concentrations and progesterone levels similar to those observed in the peak of the luteal phase. The oophorectomy group received subcutaneous implants of empty silicone rubber tubing (3 cm long) that were left in place for the duration of the treatment period. Every quarter, estrogen and progesterone plasma concentrations were determined to evaluate the adequacy of the hormone delivery system. Serum estrogen and progesterone were measured by radioimmunoassays described previously.[13]

Tissue collection and histomorphometry. At the end of the experimental period the animals were killed and necropsied. The lumbar spine was removed and cleaned of soft tissue. The dorsal arches, spinous processes, and spinal cord were removed. The lumbar vertebral bodies were transected longitudinally and fixed in 70% ethanol. Half of the L-1 vertebral body was stained in Osteochrome Villanueva stain (Polysciences, Warrington, Pa.), processed, and embedded in methyl methacrylate as described previously.[14] Blocks were sectioned midsagittally at 5 to 7 μm with a Jung-K microtome, mounted, deplasticized in xylene, and counterstained with toluidine blue before coverslipping and coding. The trabecular bone area was marked at least 1 mm away from the cortical borders, and read by one

Table I. Densitometric dual photon absorptiometry data from L-3 vertebral bodies obtained from female cynomolgus macaques that had oophorectomy and hormone replacement

Group	*Mean*	*SEM*	*Mean**	*n*

of us (M. J.). Measurements were made as described previously,[14] with a microscope equipped with a camera lucida and a computer using the Bioquant IV (R & M Biometrics, Nashville) digitizing software. Primary measurements were taken directly and included total tissue area or volume (trabecular bone plus marrow tissue) with a mean total volume of 24.44 mm^2 (SEM = 1.24); bone area or bone volume with a mean of 5.75 mm^2 (SEM = 0.35); and bone surface or perimeter with a mean of 97.32 mm (SEM = 5.01). Structural static parameters derived from primary data included L-1 trabecular bone volume percent, L-1 trabecular thickness (micrometers), L-1 trabecular number (per millimeter), and L-1 trabecular separation (micrometers).[14-16]

Ex vivo densitometry. The rest of the lumbar vertebrae were kept in 70% ethanol. Most of the longitudinally intact L-3 vertebral bodies were scanned ex vivo with a dual photon absorptiometer (Norland model 2600, Fort Atkins, Wis.). All the L-3 dual photon absorptiometry scans were performed and analyzed by one of us (S. R.). The longitudinally cut L-3 vertebral bodies were aligned and secured with rubber bands. The segments were placed ventrodorsally (the normal positioning of a live scan) on a plastic water-filled bag (approximately 2.5 cm thick) on a 6.0-mm-thick piece of Plexiglas and on top of the scanner pad. The water and Plexiglas combination modeled the absent baseline soft tissue (Rs value = 1.45*). This combination has been reported previously and provides the best ex vivo accuracy and precision.[17] Bone mineral content (in grams) and bone mineral density (grams per square centimeter) were recorded. The lumbar scans were taken at a 1.0 mm point resolution with 1.0 mm line spacing, a scan speed of 5.0 mm/sec, and a scan width of 4.0 cm. One L-3 vertebra had dual photon absorptiometry scanning 10 times for precision. The coefficient of variation for L-3 bone mineral content was 2.69% and 2.39% for L-3 bone mineral density.

*Rs is the ratio of the attenuation coefficients of the two energy beams and ranges from 1.30 (pure adipose tissue) to 1.48 (pure muscle tissue).[17]

Statistics. At necropsy the body weight of monkeys receiving estrogen replacement therapy was significantly less ($F_{2,36} = 5.37$, $p < 0.01$) than that of the animals in the other two groups by analysis of variance (BMDP Statistical Software, University of California, Berkeley, Calif.). The difference in body weight was due to the initial experimental group randomization and was not an experimental result. Correction of the various measurements for body weight without regard to the animal's height (trunk length, suprasternal notch to the pubic symphysis length in centimeters) may not be a valid method of comparing the groups. Consequently, body mass index [body weight/(trunk length/100)^2] was used as a covariate in the analyses. Means and SEM were calculated and reported for each variable. Logarithmic transformation created normality for all data. Analysis of covariance was used in the comparison of L-3 bone mineral content, L-3 bone mineral density, L-1 trabecular bone volume, L-1 trabecular bone thickness, L-1 trabecular number, and L-1 trabecular separation. Post hoc comparison between adjusted group means was performed by Tukey's test for each significantly different ($p < 0.05$ by analysis of covariance) variable.

Results

Plasma hormones. Animals that received estrogen replacement therapy (both estrogen replacement therapy and estrogen replacement therapy plus progesterone had a mean estrogen level of 221 pg/ml (SEM = 22) and those in the oophorectomy group had less than the assay's lower limit (<20 pg/ml). Mean progesterone levels during the periods of replacement ther-

apy were 9.3 ng/ml (SEM = 0.6) in the estrogen replacement therapy plus progesterone group and 0.8 ng/ml (SEM = 0.1) in the other two groups.[7]

Ex vivo dual photon absorptiometry. Dual photon absorptiometry data are summarized in Table I. For L-3 bone mineral content, no overall significant difference was found ($F_{2,24} = 2.45$; $p = 0.107$). An overall significant difference was found for L-3 bone mineral density ($F_{2,24} = 4.78$; $p = 0.018$), with significant differences between adjusted group means of the oophorectomy and estrogen replacement therapy plus progesterone groups ($p < 0.05$). No significant densitometric differences were observed between the estrogen replacement therapy and estrogen replacement therapy plus progesterone groups.

Histomorphometry. Histomorphometric results are summarized in Table II. There was no significant difference between groups of L-1 trabecular bone volume ($F_{2,35} = 1.47$; $p = 0.244$), but the estrogen replacement therapy plus progesterone group had the greatest trabecular bone volume, the estrogen replacement therapy group had less, and the oophorectomy group had the least volume even after the means were adjusted for body mass index. The L-1 trabecular bone thickness was not significantly different ($F_{2,35} = 1.87$; $p = 0.169$). However, an overall significant difference ($F_{2,35} = 4.29$; $p = 0.022$) was found for L-1 trabecular number, with significant differences between the adjusted means of the oophorectomy and estrogen replacement therapy groups ($p < 0.05$). The L-1 trabecular separation also was significantly different overall ($F_{2,35} = 3.76$; $p = 0.033$). No significant histomorphometric differences were observed between the estrogen replacement therapy and estrogen replacement therapy plus progesterone groups.

Comment

The mechanism of the action of sex hormones on bone cells is unknown and presently is an area of intense research. Both estrogens and progestins have been reported as responsible in the maintenance of bone mass in postmenopausal osteoporosis[18] and even postmenopausal use of estrogen alone has been protective against subsequent fracture in women.[19]

Histomorphometric and densitometric studies yielded similar patterns of group differences with the estrogen replacement therapy and estrogen replacement therapy plus progesterone groups having the greatest bone mineral density and trabecular bone volume of all the groups, even after body mass index adjustment. As expected, the oophorectomy group had the lowest bone values for all the histomorphometric and bone densitometric measures. Both estrogen replacement therapy and estrogen replacement therapy plus progesterone protected against oophorectomy-induced bone loss measured by either method.

Adams et al.[6] reported a significantly greater overall

extent of diet-induced coronary artery atherosclerosis in female macaques that had oophorectomy without hormone replacement. Small doses of transdermal estradiol may be as effective as oral estrogens in preventing bone loss[7] and in decreasing the risk for coronary disease.[20] Although in human and nonhuman primate females atherosclerotic plaque formation and osteopenia both are related to loss of ovarian function, each event might be the result of variable and separate mechanisms. Natural menopause has an unfavorable effect on lipid metabolism, which may contribute to an increase in the risk of coronary disease.[20] A relationship between abnormal lipid metabolism and osteoporosis presently is not known, but hormonal receptors and increased cytokine activity in bone cells are believed to be involved primarily in postmenopausal bone loss.

Hormone therapy, given for 2 years and beginning immediately after oophorectomy, appears to protect against oophorectomy-induced bone loss and coronary artery atherosclerosis in cynomolgus macaques.

We thank Drs. Thomas B. Clarkson and Robert Prichard for their support and Lori Szostack, Debbie Golden, and Dr. Agus Lelana for their assistance.

Embryopathic effects of short-term exposure to hypoglycemia in mouse embryos in vitro

Ida W. Smoak, DVM, and Thomas W. Sadler, PhD
Chapel Hill, North Carolina

The effect of short-term hypoglycemia was studied at two stages of development in postimplantation mouse embryos in vitro. Day 8 (gastrulating) mouse embryos were placed in hypoglycemic medium (60, 80, 100, or 110 mg/dl glucose) for 4 hours in which normoglycemia (120 to 150 mg/dl glucose) was restored for the remaining 44 hours of culture. Day 9 (neurulating) mouse embryos were exposed to hypoglycemia (20, 40, 60, or 80 mg/dl glucose) for 2, 4, 6, or 24 hours followed by normoglycemia for the remainder of 24 hours. At the end of culture embryos were evaluated for growth and malformations and compared with controls grown in normoglycemic medium. The results show that a 50% reduction in glucose for as little as 2 hours causes dysmorphogenesis in neurulating mouse embryos, whereas longer exposure times, more severe levels of hypoglycemia, or both are required to affect growth. Furthermore, gastrulating embryos are more sensitive to short periods of hypoglycemia than those undergoing neurulation. (Am J Obstet Gynecol 1990;163:619-24.)

Key words: Short-term hypoglycemia, malformations, mouse embryos, gastrulation, neurulation

The current approach to clinical management of the pregnant patient with insulin-dependent diabetes favors strict glycemic control instituted before conception and maintained throughout pregnancy in an attempt to reduce the incidence of malformations and perinatal mortality associated with this disease.[1, 2] As a result of aggressive management, patients with insulin-dependent diabetes are more likely to experience severe and prolonged episodes of hypoglycemia.[3, 4]

Compared with other metabolic alterations of diabetes, the teratogenicity of hypoglycemia has not been well studied. Clinical studies of pregnant human patients with insulin-dependent diabetes have yielded equivocal results concerning the potential role of hypoglycemia in congenital malformations.[4, 5] In vivo studies in rodents[6-8] have generally involved prolonged maternal hypoglycemia in which duration and level of embryonic exposure could not be accurately quantified or controlled. More recently in vitro studies have demonstrated malformations and growth retardation in rodent embryos cultured in hypoglycemic medium, but exposure times were for extended periods, generally 12 hours or longer.[8-11] In terms of embryonic development, these long exposures in rodent embryos represent several days of human gestation and therefore an unlikely duration of sustained hypoglycemia. The demonstration of malformations in rodent embryos exposed to hypoglycemia for 1 hour[12] or 8 hours in vitro[10] and 1 hour in vivo[13] suggests that short-term exposure to hypoglycemia does, in fact, interfere with normal development if the exposure occurs during critical periods of organogenesis. However, neither the minimum exposure time nor the level of hypoglycemia required to produce malformations has been defined.

Therefore this investigation evaluates the teratogenicity of short-term exposure to hypoglycemia in mouse embryos undergoing gastrulation and neurulation by systematic variations in glucose concentrations and durations of hypoglycemic exposure using whole embryo culture. This method allowed us to examine stage-dependent sensitivity to hypoglycemia and to specifically define exposure parameters at which dysmorphogenesis, growth retardation, or both occur in the mouse embryo model.

Material and methods

Whole embryo culture. The care and use of all animals in this study have been approved by the Institutional Care and Use Committee of the University of North Carolina, Chapel Hill. Randomly bred ICR mice were maintained on a 14-hour-light/10-hour-dark cycle and provided with food and water ad libitum. Females were checked for vaginal plugs the morning after overnight mating, and this day was designated day 1

of pregnancy. Pregnant females were killed by cervical dislocation on the eighth or ninth day of gestation and the uterine horns were immediately removed and placed in Tyrode's buffer. Implantation sites were dissected with watchmakers' forceps to remove conceptuses from surrounding tissues. Embryos at the appropriate stage (day 8, primitive streak; day 9, three to five somites) surrounded by an intact visceral yolk sac and ectoplacental cone were placed in medium in 30 ml culture flasks on a rotating wheel at 30 rpm and 37° C.

Day 8 (primitive streak stage) mouse embryos were cultured four to a flask as described previously[14] in a combination of mouse serum, rat serum, and Tyrode's buffer for the first 24 hours of culture. Hypoglycemic medium was prepared with 25% serum from mice injected intraperitoneally with 5 IU regular insulin 1 hour before blood collection and 50% serum from rats injected intraperitoneally with 50 IU regular insulin 2 to 3 hours before blood collection. Serum was immediately centrifuged, heat inactivated, and treated with 2.5 μl/ml streptomycin and frozen at −20° C. The remaining 25% of culture medium consisted of Tyrode's buffer and sufficient concentrated (50 mg/ml) β-D-glucose to produce the appropriate glucose concentrations. Control medium was prepared in the same manner to produce glucose concentrations between 120 and 150 mg/dl, the normal range for rodents. Glucose measurements were made using a model 27 industrial analyzer (Yellow Springs Instruments, Yellow Springs, Ohio). After an initial 4-hour exposure to 60, 80, 100, 110, or 120 to 150 mg/dl glucose, the glucose concentration of the medium was measured and hypoglycemic medium was made normoglycemic (120 to 150 mg/dl glucose) for the remainder of the first 24 hours with the addition of a small amount of 50 mg/ml β-D-glucose. Embryos were then transferred individually to 2.5 ml normoglycemic medium containing 75% rat serum and 25% Tyrode's buffer for the second 24 hours in culture. Flasks were aerated at 12-hour intervals with a gas mixture of 5% oxygen, 5% carbon dioxide, and 90% nitrogen, and at 48 hours with 20% oxygen, 5% carbon dioxide, and 75% nitrogen. Cultures were terminated at 48 hours.

Day 9 embryos (three to five somites) were placed individually in 2.5 ml hypoglycemic or control medium. Hypoglycemic medium consisted of 75% serum from rats injected intraperitoneally with 50 IU regular insulin 2 to 3 hours before blood collection. The remaining 25% consisted of Tyrode's buffer and a small amount of 50 mg/ml β-D-glucose, as necessary, to produce the appropriate glucose concentrations. Control medium was prepared in the same manner, or with 75% normal rat serum and 25% Tyrode's buffer; both methods produced glucose concentrations between 120 and 150 mg/dl. Treated embryos were exposed to 20, 40, 60, or 80 mg/dl glucose for 2, 4, or 6 hours; the glucose concentration of the medium was then measured, and a small amount of 50 mg/ml β-D-glucose was added to the medium to bring the glucose concentration to control levels (120 to 150 mg/dl) for the remainder of the 24-hour culture period. Additional embryos were exposed to each level of hypoglycemia for the entire 24-hour culture period. Treated embryos were compared with controls cultured for 24 hours in normoglycemic medium. Flasks were aerated initially and at 12 hours with 5% oxygen, 5% carbon dioxide, and 90% nitrogen and at 24 hours with 20% oxygen, 5% carbon dioxide, and 75% nitrogen. Cultures were terminated at 24 hours.

Assessment of embryos. Embryos were removed from culture (day 8, 48 hours; day 9, 24 hours) and examined under a dissecting microscope for gross malformations, rotation, heartbeat and circulation, and somite number. The majority of embryos in each group were frozen for total protein determination according to the Lowry method[15] as an assessment of embryonic growth. Several embryos were processed for scanning electron microscopy to illustrate representative malformations using Sorenson's glutaraldehyde fixative and osmium postfixation followed by dehydration in graded alcohols, critical point drying, and argon coating. Statistical analysis was performed with an analysis of variance.

Results

Day 8 embryos. Control embryos placed in culture at day 8 (primitive streak stage) and grown for 48 hours attained a size and conformation similar to that of day 9 control embryos grown for 24 hours (i.e., the normal morphologic features of day 10 embryos; Fig. 1, *1* and *3*). Ten of 64 (14%) day 8 control embryos failed to grow normally and exhibited incomplete rotation, exencephaly, or both.

Day 8 embryos exposed to 4 hours of hypoglycemia followed by normoglycemia for the remainder of 48 hours showed high malformation rates at all glucose concentrations tested (60, 80, 100, and 110 mg/dl). Defects included poor overall growth and rotation, failure of cranial neural tube expansion and closure, dysmorphic optic primordia, and incomplete cardiac looping (Fig. 1, *2*). Total protein measurements and somite numbers showed a significant growth retardation of day 8 embryos after short-term exposure to hypoglycemia (Table I), and both dysmorphogenesis and growth retardation were more severe in day 8 than day 9 embryos after comparable hypoglycemic exposures.

Glucose concentrations decreased by a mean 2.2 mg/dl in hypoglycemic media and 4.0 mg/dl in control media during the first 4 hours of culture.

Day 9 embryos. No difference was observed in the

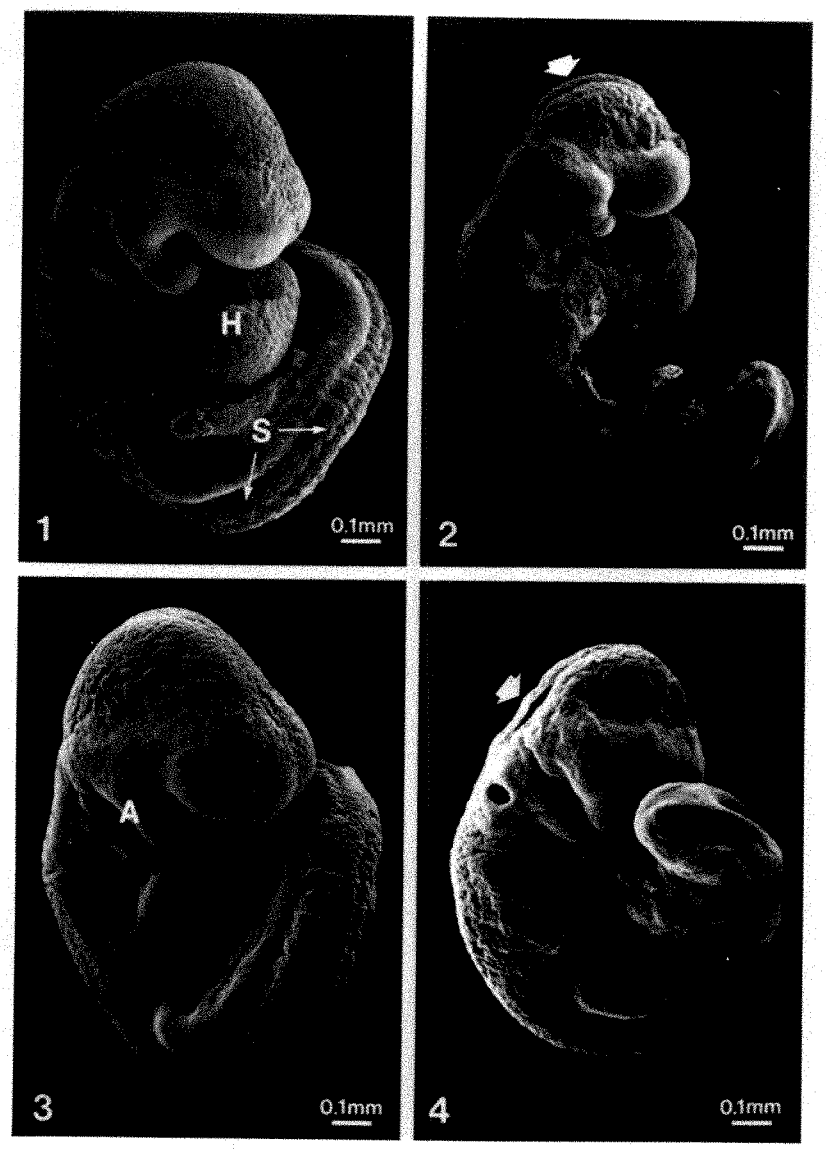

Fig. 1. 1, Day 8 (gastrulation stage) mouse embryo cultured 48 hours in normoglycemic medium showing normal rotation, closed and expanded cranial neural tube, and 20 to 23 somite pairs. Heart *(H)*, somites *(S)*. (×70). **2,** Day 8 mouse embryo cultured 4 hours in hypoglycemic medium (60 mg/dl glucose) and 44 hours in normoglycemic medium showing incomplete growth and rotation, failure of cranial neural tube expansion and closure *(arrow)*, and abnormal cardiac looping. (×70). **3,** Day 9 (three to five somite pairs) mouse embryo cultured 24 hours in normoglycemic medium showing normal rotation, closed and expanded cranial neural tube, and 20 to 23 somite pairs. (×70). **4,** Day 9 mouse embryo cultured 4 hours in hypoglycemic medium (60 mg/dl) and 20 hours in normoglycemic medium showing incomplete expansion and closure of cranial neural tube *(arrow)*, abnormal closure of posterior neuropore, and 20 to 22 somite pairs. (×70).

growth and development of day 9 (three to five somites) mouse embryos cultured for 24 hours in control medium (120 to 150 mg/dl glucose) from normal serum or glucose-supplemented serum collected from rats treated with insulin. Embryos rotated into a fetal-like position and developed a regular heartbeat and visceral yolk sac circulation. Somite pairs increased to 18 to 22, and the neural tube closed completely (Fig. 1, *3*) with the exception of the posterior neuropore, which normally remains open at this stage of development. One of 53 (1.9%) control embryos failed to develop normally and exhibited exencephaly and a narrow optic vesicle.

Embryos exposed to hypoglycemia demonstrated deficiencies in rotation, heartbeat and circulation, somite number, and neural tube closure, particularly at lower glucose concentrations and longer periods of exposure (Table II). Gross malformations resulting from hypoglycemic exposure typically involved deficient expan-

sion and closure of the cranial region of the neural tube (Fig. 1, *4*). Less frequent defects included abnormal closure of the posterior neuropore, dysmorphic or small optic primordia, hypoplastic visceral arches, incomplete cardiac looping, and pericardial swelling.

Malformation rates increased with longer exposure times at each level of hypoglycemia and were significantly elevated above the control level in all but the groups exposed to 80 mg/dl for 2 and 4 hours. In addition, for each period of hypoglycemic exposure, malformation rates increased as glucose concentrations decreased (Table II). A two-way analysis of variance demonstrated a significant interaction between glucose concentration and duration of hypoglycemic exposure with respect to malformation rates.

Embryonic growth was assessed by measuring total protein content and monitoring somitogenesis in individual embryos. Protein content was significantly decreased in embryos exposed to 20 or 40 mg/dl glucose for 4, 6, or 24 hours, and to 60 mg/dl for 24 hours compared with controls (Table II). A consistent trend in decreasing protein content with increasing duration of hypoglycemic exposure occurred in embryos cultured in 20, 40, or 60 mg/dl glucose. There was no decrease in protein content at any duration of exposure in embryos cultured in 80 mg/dl glucose. These results closely paralleled the effect of hypoglycemia on somitogenesis (Table II).

Glucose concentrations decreased by a mean 3.1 mg/dl in hypoglycemic media and 4.0 mg/dl in control media during the first 2 to 6 hours of culture.

Comment

The incidence of congenital malformations in the offspring of patients with insulin-dependent diabetes remains elevated despite current emphasis on improved metabolic control.[16] Recent clinical practices with intensive insulin therapy have increased the susceptibility of patients with insulin-dependent diabetes to hypoglycemic episodes,[3, 4] making hypoglycemia an important factor to consider for its teratogenic potential. The majority of previous investigations in this area have used exposure times in rodent embryos equivalent, in terms of developmental stages, to several days of human gestation (one day of mouse development is equivalent to approximately 5 days in the human). This study represents the first systematic evaluation of hypoglycemia in the mouse embryo model at levels and durations of hypoglycemia more consistent with those presumably experienced by embryos of human patients with insulin-dependent diabetes.

To define levels and durations of hypoglycemia that produce abnormal growth and development, we exposed day 9 (neurulating) mouse embryos in vitro to 20, 40, 60, and 80 mg/dl glucose, representing 16%, 32%, 48%, and 64%, respectively, of normal blood glucose in a pregnant mouse (125 mg/dl). Hypoglycemic exposures were for 2, 4, 6, and 24 hours, approximately equivalent to 8 to 10 hours, 16 to 20 hours, 24 to 30 hours, and 5 days, respectively, in terms of human embryonic development during the same period of neurulation.[17] Our results demonstrate that neurulating mouse embryos exposed for as little as 2 hours to glu-

cose concentrations of 60 mg/dl or less show increased malformation rates when evaluated after 24 hours in culture. Growth retardation, as judged by total protein content and somitogenesis, occurs after 4 or more hours at glucose concentrations ≤40 mg/dl. Risk of dysmorphogenesis or growth retardation increases with increasing severity of exposure parameters (i.e., longer duration of hypoglycemia and lower glucose concentration).

Our results also suggest that younger, gastrulating embryos are more sensitive to short-term hypoglycemic exposure than those undergoing neurulation. Thus a 52% reduction (to 60 mg/dl) from normal glucose levels caused significantly elevated malformation rates in day 9 embryos, whereas a reduction of only 12% (to 110 mg/dl) from normal glucose levels produced abnormal growth and development in a significant number of day 8 embryos. Overall, day 8 embryos were more sensitive than day 9 embryos undergoing whole embryo culture, as evidenced by malformation rates of controls (14% vs 2%). This is consistent with previous studies and suggests a greater vulnerability of younger embryos to experimental manipulation.

Mammalian embryos are highly dependent on glucose as their primary energy source during the periods of gastrulation, neurulation, and early organogenesis[18] and are therefore sensitive to deficient glucose levels during these periods of development. Interestingly, hypoglycemia appears to have greater teratogenic potential than the more classic metabolic alterations of diabetes mellitus such as hyperglycemia and hyperketonemia. For example, glucose and ketone bodies must be experimentally elevated many times above normal levels for extended periods of time (24 to 48 hours) to cause consistent embryonic abnormalities in rodent embryos,[19, 20] whereas a 52% reduction from normal glucose levels is detrimental after only 2 hours in the neurulating mouse embryo. Therefore mild maternal hyperglycemia during early pregnancy may be less detrimental to the developing embryo than the risk of

hypoglycemic exposure resulting from overaggressive insulin therapy. Since stages immediately after implantation appear to be the most sensitive to induction of the diabetic embryopathy, management of the diabetic before conception is essential.

Ovarian granulosa cell tumorigenesis in SWR-derived F1 hybrid mice: Preneoplastic follicular abnormality and malignant disease progression

Barbara J. Tennent, PhD, Kathryn L. Shultz, BS, John P. Sundberg, DVM, PhD, and Wesley G. Beamer, PhD

Bar Harbor, Maine

A high incidence (27.5%; 174 of 633) of spontaneous, malignant ovarian granulosa cell tumors develop in (SWR × SWXJ-9)F1 hybrid females between 3 and 6 weeks. Granulosa cell tumors developed in predictable stages, starting as preneoplastic lesions appearing as hyperemic follicles on the ovarian surface. These follicles were characterized by hypertrophied theca, degenerating oocytes, and large fluid- or erythrocyte-filled antra lined by irregular masses of granulosa cells. Rapidly proliferating granulosa cells filled the antra and the theca/interstitial cells became more dysplastic as granulosa cell tumors developed. Thus the morphology of the preneoplastic lesion suggests that disturbed mechanisms for normal follicular development underlie granulosa cell tumor initiation. Estradiol treatment before but not after preneoplastic lesions appeared inhibited granulosa cell tumor formation. By 6 to 9 months 42% of these mice show metastases in major abdominal and thoracic organs. Thus this model can be experimentally analyzed both for mechanisms of granulosa cell tumor initiation and subsequent malignant progression. (Am J Obstet Gynecol 1990;163:625-34.)

Key words: Mouse ovarian granulosa cell tumorigenesis, preneoplastic follicles, malignant progression

A novel mouse model for inherited susceptibility to granulosa cell tumors of the ovary has recently been described.[1-3] The granulosa cell tumors arise spontaneously in pubertal SWR/JBm, certain of their F1 hybrids, and some SWR × SJL derived recombinant inbred (SWXJ) strains of mice carrying the susceptible allele of *Gct* on chromosome 4.[3] Granulosa cell tumor incidence varies among strains and is governed by a small number of genes, some involving steroid metabolism regulation.[2] The SWR granulosa cell tumor bears a striking resemblance to human juvenile granulosa cell tumors found in young girls from infancy through menarche.[4, 5] Common features of this neoplasm in SWR mice and humans include early onset in ovaries with intact oocytes and follicles, depressed serum gonadotropins and aberrant steroidogenesis, similar histopathologic features of primary tumors, and malignant potential. Granulosa cell tumorigenesis in this model contrasts sharply with that found in other experimental and spontaneous rodent models in which oocyte deletion appears to be a prerequisite for tumor development.[6] In these models granulosa cell tumor formation is usually very slow and is preceded by mesothelial adenoma formation.[6] Furthermore, spontaneous granulosa cell tumors in mice[6] and rats[7] are typically unilateral and slow growing. Spontaneous granulosa cell tumors also occur in several domestic animal species, including cat, dog, sow, sheep, cow, and horse.[8, 9] Granulosa cell tumors also usually occur in adult animals, although cases in younger cats,[10] horses,[11] and calves[9] have been reported. In these species granulosa cell tumors are rarely bilateral and malignant potential varies with most malignancies found in mares and cats.[9]

Previous efforts to study the etiology of granulosa cell tumors in SWR-derived mice have been hampered by the relatively low spontaneous incidence found in susceptible strains.[1] In recent studies of genetic control of granulosa cell tumor susceptibility, a stock was created that is characterized by several features permitting investigations of all phases of granulosa cell tumorigenesis. The (SWR × SWXJ-9)F1 hybrid described in this article has a tightly circumscribed developmental age for granulosa cell tumor initiation, a remarkably high spontaneous granulosa cell tumor incidence, and marked potential for malignant progression. We describe the histopathology of preneoplastic ovaries, a longitudinal study of granulosa cell tumor development in mice identified as having macroscopic lesions in their

ovaries at puberty, and the morphology and incidence of primary and metastatic granulosa cell tumors.

Material and method

Mice. Mice used in these experiments were maintained according to the guidelines for care and use of laboratory animals established by the National Institutes of Health. Matings were made between progenitor SWR strain (low granulosa cell tumor incidence) and SWXJ-9 strain (higher granulosa cell tumor incidence) mice.[1] Data in this report were gathered on (SWR × SWXJ-9)F1 hybrid female mice aged 3 weeks to 9 months. Mice were raised in a research colony at The Jackson Laboratory, maintained under 12-hour light-dark cycles. Mice were given pasteurized Wayne Lab Blox diet (crude protein, 24%; fat, 4%; fiber, 4.5%; ash, 5.9%; and vitamin and mineral fortified; Wayne Research Animal diets, Chicago) and chlorinated (10 to 20 ppm sodium hypochlorite; pH 2.8 to 3.2) water ad libitum. Two to four mice were housed in polycarbonate cages (13 × 28 × 15 cm) with white pine shavings for bedding. Granulosa cell tumorbearing mice retained for longitudinal studies were identified by aseptic laparotomy with the animals under general anesthesia (tribromoethanol, 0.25 mg/gm of body weight). Ovaries were exteriorized through bilateral flank incisions for inspection. After careful return of tumors or normal ovaries to the abdominal cavity, the muscle and skin wounds were surgically closed. Extra heat was provided for mice recovering from anesthesia before returning them to the animal room. Mice were killed by cervical dislocation for necropsy.

Preneoplastic lesions. The first studies were conducted to determine whether grossly apparent changes in juvenile ovarian morphology were predictive of granulosa cell tumor development and to characterize preneoplastic histologic changes associated with macroscopically identifiable lesions at various ages.

Experiment 1. To establish the prognostic validity of gross observations of preneoplastic ovaries, laparotomies were performed on groups of 50 to 60 mice at 28 or 42 days of age. Visual abnormalities of the ovary such as hyperemic follicles or granulosa cell tumor foci were noted, and mice were retained until 10 weeks of age when they were reinspected for granulosa cell tumors.

Experiment 2. To determine the sequence of morphologic changes during granulosa cell tumor development, separate groups of mice were killed at 22, 28, 32, 36, or 42 days of age. Biologic parameters of body, uterine, and ovarian weights and vaginal opening and cytology were determined to assess developmental status of mice at these ages. Ovaries were removed and fixed in Bouin's solution for routine histologic processing for light microscopy. Additional samples were fixed in Fekete's acid-alcohol formalin or neutral buffered 10% formalin, or were frozen before sectioning and stained with oil red O for lipid. Tissues were embedded in paraffin, sectioned at 6 μm, and sections were stained with hemotoxylin and eosin, ammoniacal silver for reticulin, Gomori's stain for iron, or periodic acid–Schiff stain for carbohydrate.

Experiment 3. To determine the effect of inhibiting ovulatory processes on granulosa cell tumor initiation, mice were treated with estradiol or cholesterol at 21 to 22 (preovulatory) or 29 to 36 (periovulatory) days of age. Mice were assigned to treatment groups by split-litter method, anesthetized as described above, and 1 cm silicone rubber capsules filled with cholesterol or 0.8% estradiol in cholesterol prepared as previously described[2] were surgically inserted beneath the skin in the scapular region. Necropsy was done at 56 to 70 days of age; body and organ weights, vaginal cytology, and presence of granulosa cell tumors were recorded. Representative ovaries were fixed for histologic examination.

Metastatic incidence and granulosa cell tumor morphologic features. To evaluate metastatic incidence, 65 pairs of granulosa cell tumor-bearing and littermate control mice were identified by laparotomy at 10 weeks of age and maintained until 7 to 9 months of age. Mice were weighed weekly and inspected for visible signs of advancing disease, such as poor coat quality, edematous appearance or sudden weight loss, pale ears indicative of anemia, lethargy, or labored breathing. Mice that appeared moribund were killed and inspected for metastases. Remaining mice were killed at indicated ages. Macroscopically visible nodules were recorded and fixed for histologic confirmation of granulosa cell tumor tissue. A subset of 15 (SWR × SWXJ-9)F1 mice with granulosa cell tumors were necropsied at 6 to 7 months of age for complete pathologic analyses. Ovaries, brain, lung, pancreas, stomach, duodenum, ileum, jejunum, cecum, colon, salivary glands, uterus, cervix, vagina, spleen, heart, esophagus, trachea, adrenal gland, both kidneys, skeletal muscle, liver, gall bladder, spinal cord, vertebrae, three sections of decalcified skull, urinary bladder, thymus, thyroid, and multiple lymph nodes were removed and fixed in Fekete's acid-alcohol formalin. Tissues were processed for light microscopy as previously described.

Results

Preneoplastic lesions

Experiment 1. In the study of preneoplastic progression, 12 of 57 (21%) mice examined at 28 days had macroscopically abnormal ovaries that were characterized by hyperemic follicles on the surface, but in most cases the ovaries were not enlarged. The ovaries of these 28-day F1 hybrid mice contained large antral fol-

licles; however, first ovulation had not occurred. At 10 weeks, 11 of the 12 (92%) ovaries with hyperemic follicles had progressed to granulosa cell tumors. One ovary had only an erythrocyte-filled cyst that was composed of a few layers of granulosa cells lining a cystic follicle. In addition, four mice with macroscopically normal ovaries at 28 days of age had granulosa cell tumors by 10 weeks of age. Thus the overall granulosa cell tumor incidence for this group of mice was 26.3% (15/57).

Twelve of 50 mice examined at 42 days of age had granulosa cell tumors that were characterized by an enlarged ovary with viable-appearing neoplastic tissue enclosed by the ovarian bursa, and striking increases in the ovarian vasculature. All of these mice still had granulosa cell tumors at 10 weeks of age. No additional tumors were found in mice that had normal ovaries at 42 days of age. Thus in (SWR × SWXJ-9)F1 mice, granulosa cell tumors develop between the third and sixth week of life, coincident with the transitional period of puberty.

Experiment 2. At 22 days of age all ovaries appeared normal by visual inspection, were small and kidney-shaped, with no corpora lutea visible. Histologic examination revealed that they were comprised mainly of primary follicles or follicles with several layers of granulosa cells. Formation of antral follicles was in early stages.

Between 28 and 32 days ovaries with preneoplastic lesions exhibited remarkably rapid changes in morphology. Several disturbances in follicular development of normal ovaries (Fig. 1, *a*) were observed. First, incipient granulosa cell tumor foci were observed in antral follicles (Fig. 1, *b*) with oocytes still present (Fig. 1, *c*). These follicles were characterized by degenerating oocytes frequently surrounded by proliferating granulosa cells in structures resembling an enlarged cumulus oophorus. Necrotic granulosa cells were observed at the base of this cellular mass and sometimes these masses were detached (verified in serial sections) from granulosa cells lining the antrum. Alternatively, the oocyte was also observed embedded in a proliferating mass of mural granulosa cells. Thus, tumorigenesis did not appear to be confined to a single type of granulosa cell. In other follicles wherein oocyte remnants were no longer visible, proliferating granulosa cells filled most of the follicular space (Fig. 1, *d*). By 32 days oocytes were not commonly observed in preneoplastic follicles. A second characteristic was the presence of erythrocytes in the antra of follicles. Capillaries were observed traversing the theca and penetrating the granulosa layers, providing a source for the blood (Fig. 2, *a*). A third feature was the loss of basement membrane demarcation between the preneoplastic follicle wall and the theca (Fig. 2, *b* and *c*). The thecal/insterstitial cell compartment was proliferating as evidenced by mitotic figures, became increasingly hypertrophied, and oil red O-stained sections revealed abundant, large lipid droplets. Granulosa cell lipid was also demonstrable but appeared in the form of very small droplets. During this period the demarcation between granulosa and theca layers became less distinct; theca and granulosa cells showed a tendency to interdigitate (Fig. 2, *b*). Granulosa cells at these borders appeared hypertrophied or necrotic (Fig. 2, *b* and *c*). In silver stained–sections, reticulum fibers were clearly observed in the theca, circumscribing the granulosa compartment of normal follicles as part of the basal lamina. Reticulum fibers were also prominent in the theca-interstitium of preneoplastic follicles but were no longer continuously delineating the granulosa compartment. The remaining nontumorous follicles in preneoplastic ovaries were small and most contained degenerating oocytes.

Many of the ovaries that did not have obvious preneoplastic lesions were characterized by multiple atretic antral follicles with prominent theca, degenerating oocytes, and granulosa cells with pyknotic nuclei.

At 36 days morphologic features transitional between preneoplasia and neoplasia were observed. Some of the aberrant follicles were filled with neoplastic granulosa cells showing multiple mitotic figures. Peripheral granulosa cells were frequently vacuolated and elongated toward the center of the cysts. In some instances, small patches of loosely adherent granulosa cells were detached from the granulosa cell mass and were found within venous or lymphatic channels. Other ovaries remained composed primarily of large hemorrhagic follicles with irregular layers of granulosa cells lining the cysts. Thecal cells were dysplastic and were either hypertrophied or retained an elongated fusiform shape. Mitotic figures were frequently observed. Some thecal interstitial cells were arranged in clusters of luteinized theca. Areas of hypertrophied thecal/interstitial cells not clearly associated with a developing granulosa cell tumor focus were sometimes observed. Staining with oil red O revealed the presence of lipid in these hypertrophied thecal cells. The contralateral ovary at this stage sometimes showed preneoplastic follicles. Alternatively, some ovaries appeared normal and showed evidence of recent ovulation and corpora lutea formation.

At 42 days a variety of morphologic patterns were observed in developing granulosa cell tumors. This appeared to be a time of rapid growth for most tumors. The most striking morphologic features were the large masses of granulosa cell tumor cells separated by small compressed patches of thecal/interstitial cells (Fig. 3, *a*) and the high number of mitotic figures (three to seven) per single high-power field (Fig. 3, *b*). In some

(Original magnification ×25.) **b,** Preneoplastic, 29-day ovary showing multifocal cystic follicles with granulosa cells arranged in multilayered irregular masses, rather than a single layer of flattened cells typical of polycystic ovarian disease. (Original magnification ×25.) **c,** Abnormal follicle with central mass of granulosa cells attached to follicle wall. The center of the mass contained erythrocytes and cellular debris, whereas a degenerating oocyte can be seen in the periphery of the mass *(arrow).* (Original magnification ×62.5.) **d,** Another 29-day ovary with a majority of this preneoplastic cystic follicle filled with loosely adherent granulosa cells. (Original magnification ×62.5.)

areas granulosa cell tumor cells were hypertrophied and resembled luteinized granulosa cells. Staining with oil red O revealed lipid accumulation in these cells. Some of the larger granulosa cell tumors had necrotic regions or individual cells with pyknotic nuclei. The pattern of granulosa cell tumor cell arrangement was either macrofollicular or solid, with areas of fluid- or erythrocyte-filled cysts. Areas of thecal/interstitial cell involvement were most clearly seen in slides stained for reticulum fibers. Reticulum fibers were observed surrounding thecal cells but were not seen in the rapidly proliferating granulosa cell masses. The degree of thecal involvement varied considerably but was not a prominent feature. The thecal/insterstitial cells were markedly hypertrophied, frequently vacuolated, and interdigitated with small blood vessels. In sections stained for iron, deposits were observed in cells within the thecal/interstitial compartment, but not within the granulosa cell tumor cell mass. In some cases small follicles with oocytes present were observed at the periphery of the granulosa cell tumor mass.

At 70 days of age granulosa cell tumors were characterized by a macrofollicular pattern encircled by thecal/interstitial tissue that varied in thickness from a few cell layers to thick areas of hypertrophied cells with foamy cytoplasm staining positively for lipid. In some regions of granulosa cell tumor cells, multiple mitotic figures were observed, whereas other areas of the tumors appeared quiescent in growth or undergoing necrosis. Variably sized erythrocyte- or glycoprotein-filled

cysts were prominent throughout the macrofollicular masses of tumor cells. In some cases normal primary follicles with degenerating oocytes, restricted to the periphery of the granulosa cell tumor mass, were observed.

In conjunction with the morphologic data gathered during the peripubertal period, measurements of reproductive maturation were also obtained from separate groups of mice. Table I shows that the interval from 22 to 38 days was a period of rapid ovarian steroidogenic development as evidenced by significant increases in ovarian and uterine weights and in the percentage of females with open vaginas. Thus preneoplastic lesions arose simultaneously with the onset of reproductive maturation.

Experiment 3. The results of estradiol treatment on granulosa cell tumor incidence are presented in Table II. There was a striking difference in the effect of estradiol on granulosa cell tumor incidence between the two age groups. At 21 to 22 days estradiol treatment significantly suppressed granulosa cell tumor incidence, whereas no effect was found in the 29- to 36-day old group. In this latter group, there was no apparent correlation between age at capsule insertion and granulosa cell tumor incidence. In contrast, estradiol exerted a similar effect on body weight and vaginal cytology in mice of both groups. Histologic examination of estradiol-treated nontumorous ovaries demonstrated that ovulation was blocked as evidenced by the absence of corpora lutea. Ovaries contained variably sized antral follicles, many of which showed signs of atresia, including granulosa cells with pyknotic nuclei, degenerating oocytes, and prominent theca. There was no evidence of preneoplastic follicles. Granulosa cell tumors from the estradiol-treated mice did not appear to differ morphologically from those found in the cholesterol-treated control mice. In contrast, ovaries from the cholesterol-treated mice were normal and they contained follicles in various stages of development and corpora lutea appropriate to cycling mice.

Metastatic progression

Frequency. The incidence of primary granulosa cell tumors in the (SWR × SWXJ-9)F1 mice at the time of writing is 27.5% (174/633). A group of 66 granulosa cell tumor host mice was used to establish metastatic incidence and primary granulosa cell tumor location. The data, presented in Table III, reveal that the majority of primary granulosa cell tumors were bilateral, with no trend for laterality in the remaining tumors. By 6 to 9 months of age primary and metastatic disease became lethal. There was a high percentage (42%) of mice with metastatic disease. Metastases were most com-

Fig. 2. (Original magnification ×62.5.) Normal ovarian tissue was no longer visible in this ovary. **b,** Multiple mitotic figures observed in granulosa cell tumor mass of **a.** (Original magnification ×250.)

Table I. Reproductive maturation parameters for (SWR × SWXJ-9)F1 hybrid female mice without ovarian granulosa cell tumors

Age (days)	*Body weight (gm)*	*Ovarian weight (mg)*	*Uterine weight (mg)*	*Vagina open (%)*
22	8.70 ± 0.25	2.02 ± 0.11	8.18 ± 0.54	0
29	13.11 ± 0.40	3.18 ± 0.12	30.15 ± 5.22	92
38	15.91 ± 0.33	5.45 ± 0.21	80.21 ± 9.14	100

monly found within renal lymph nodes, liver, and lungs. Other tissues with a lower frequency of metastatic nodules include spleen, diaphragm, stomach, mediastinum, skeletal muscle, abdominal connective tissue, and muscle, kidney, and pancreatic lymph nodes. Tissue examined and found free of metastatic nodules were brain, small and large intestine, salivary glands, uterus, vagina, heart, esophagus, trachea, adrenal glands, urinary bladder, thymus, and thyroid gland. Ascites was occasionally observed in older granulosa cell tumor host mice.

Morphology. At necropsy primary granulosa cell tumors ranged in size from 3 to 4 mm to more than 25 mm in diameter. Twenty-six primary granulosa cell tumors had macroscopically evident moderate to extensive areas of necrosis. In rare instances a tumor appeared completely regressed. Regressed granulosa cell tumors showed focal necrosis, congestion of medium and large veins, and effacement by foamy round pigment-laden cells. Follicles containing oocytes were not present. Growing primary tumors consisted of retiform, micro- or macrofollicular patterns. Particularly in granulosa cell tumors with the microfollicular arrangement (Fig. 4, *a*), small spheroids of detached granulosa cells could be seen entering lymphatic or blood vessels (Fig. 4, *b*). Cells within these spheroids had frequent mitotic figures. Granulosa cells were characterized by scant amphophilic cytoplasm, small oval nuclei with coarsely clumped chromatin, and a single small nucleolus. Nuclear grooving was not observed in tissues fixed in Bouin's or Fekete's solutions. Structures resembling Call-Exner bodies, microcysts containing material that stained positive for glycoprotein by the periodic acid–Schiff stain, were also observed. Areas of necrosis, some with fibrin thrombi, were prominent in the larger tumors. The granulosa cell tumors also had large congested veins. An additional feature of all tumors was the presence of large, multinucleated, foamy cells—possibly macrophages—containing a diffuse golden brown pigment that stained positively for iron. Some of these cells also contained dark brown, finely granular cytoplasmic pigment. Small, scattered foci of osteoid were present in approximately half of the granulosa cell tumors (Fig. 4, *a*). These were always located in areas in which there were numerous lymphatics and small veins. Occasionally areas of luteinized thecoma, distinguished by positive staining for reticulum and lipid, were observed. Local invasion through the ovarian bursa was evident in all cases, indicating early visceral implantation of tumor cells.

The histologic appearance of metastatic nodules was strikingly similar to that of the primary granulosa cell tumors. Metastases often had a solid pattern with little evidence of necrosis and frequent mitotic figures. Less

frequently, microfollicular (Fig. 4, *c*) or macrofollicular arrangements of granulosa cell tumor cells were observed. Very large metastatic nodules occasionally had areas of focal necrosis or accumulation of dark brown pigment.

Nontumorous contralateral ovaries were small in size and contained a small number of follicles with scattered individual cell necrosis and numerous small colloid-filled microcystic structures.

Comment

The (SWR × SWXJ-9)F1 hybrid has provided a unique opportunity to identify morphologic changes at all stages of granulosa cell tumorigenesis associated with tumor initiation, primary tumor development, and metastatic progression. In these F1 hybrid mice, granulosa cell tumors occur simultaneously with recruitment of the first group of follicles during ovarian maturation, form in antral follicles with intact oocytes, are commonly bilateral, grow rapidly, and become metastatic with high frequency.

The finding of macroscopically visible ovarian abnormalities that are prognostic for granulosa cell tumor development by 28 days of age permitted identification of tumor-destined individuals at preneoplastic stages. Histologic examination of such ovaries revealed features that were not observed in previous microscopic examination of established primary granulosa cell tumors in adult mice.[1] The development of morphologic abnormalities in preneoplastic ovaries offers some insights into mechanisms underlying granulosa cell tumorigenesis in the SWR model. First, within the follicular compartment, no ovarian abnormalities were detected at 22 days before formation of large antral follicles. Identifying preneoplastic changes just 6 to 7 days later defines this time as the beginning of the critical period for tumor initiation. Preneoplastic changes were initiated only in antral follicles, with degenerating oocytes often present. Normal follicles in earlier stages of development could be seen on the periphery of ovaries with developing granulosa cell tumors, and there was no evidence of neoplastic transformation of granulosa cells within these small follicles. Thus the granulosa cell tumor did not appear to grow by recruiting relatively undifferentiated granulosa cells from nearby normal follicles. This suggests that one or more of an array of intricately balanced endocrine, paracrine, and autocrine factors[12] regulating normal granulosa cell proliferation and differentiation may be part of granulosa cell tumor-initiating stimuli. Furthermore, only the relatively differentiated granulosa cells from antral follicles may be susceptible to tumor-initiating stimuli. This hypothesis is strengthened by the finding that granulosa cell tumor incidence was suppressed in these F1 hybrid mice by treatment with estradiol at 21 to 22 days before development of large antral follicles. Estradiol treatment also suppressed granulosa cell tumor initiation in SWXJ-9 progenitor strain mice.[1] Once the preneoplastic lesions had formed, estradiol did not prevent subsequent tumorigenesis. Thus we speculate that estrogen exerts an effect on the granulosa cell tumor-initiating stimuli rather

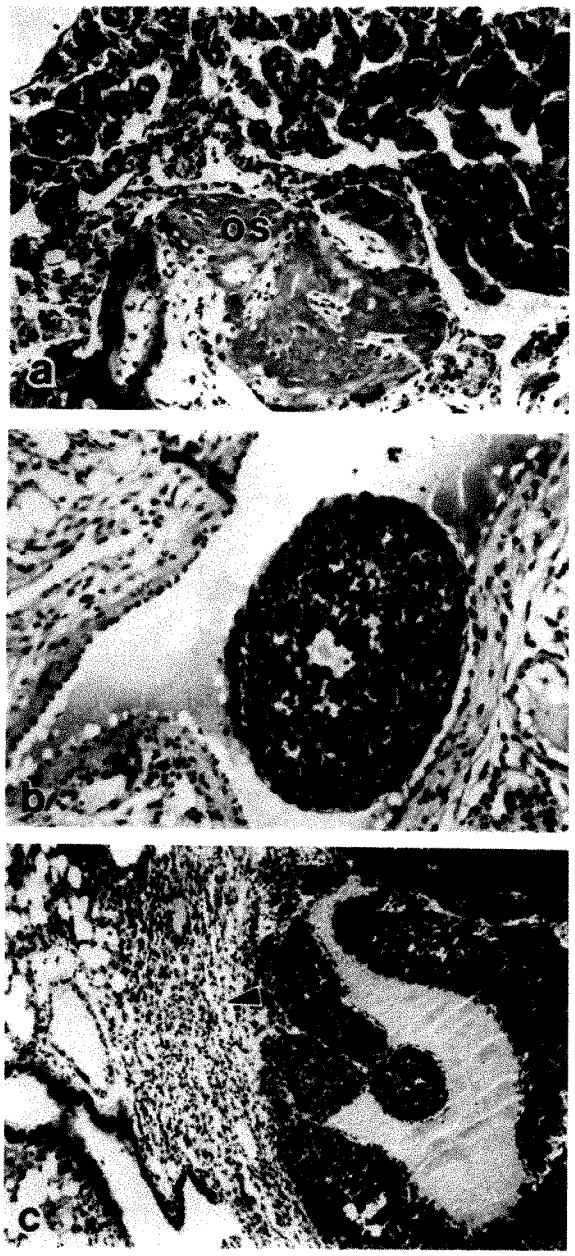

Fig. 4. Primary and metastatic granulosa cell tumors in adult mice. **a,** Primary granulosa cell tumor displaying microfollicular arrangement with adjacent osteoid (os) in central portion of tumor. Cells arranged in this pattern were bathed in serous or erythrocyte-filled fluid and had substantially less necrosis than cells arranged in more solid or macrofollicular patterns. (Original magnification ×125.) **c,** Pulmonary metastatic nodule compressing normal lung tissue *(arrow)* at left side of photomicrograph. The metastatic cells are arranged in pseudofollicular pattern with a peduncle of granulosa cell tumor cells reminiscent of those seen in preneoplastic follicles. (Original magnification ×62.5.)

than on tumor growth–supportive mechanisms. There are several ways in which estradiol could suppress granulosa cell tumor initiation. For example, estradiol treatment affects granulosa cell development both indirectly via suppression of pituitary gonadotropin release and directly via modulation of steroidogenic enzyme activities[13] and receptor numbers for gonadotropin and other growth factors.[12]

A second feature of preneoplastic lesions that offers insight into tumorigenic mechanisms is the hypertrophy and hyperplasia of the thecal/interstitial cell compartment. The recognition of abnormalties in this compartment during granulosa cell tumor initiation is an important finding because there are several likely interactions between thecal/interstitial cells and preneoplastic granulosa cells. For example, during the transition from immature to adult ovarian status, there are definitive changes in steroidogenesis as biologically less active products are replaced by more potent androgens and estrogens.[14] In normal adult ovaries, the thecal/interstitial cell compartment is the source of androgens, and hypertrophy of this compartment is associated with increased androgen production both in atretic follicles and in polycystic ovarian disease.[15] Androgens are also involved in granulosa cell tumor initiation in the SWR model. Granulosa cell tumor incidence is increased in both SWR and SWXJ-9 progenitor strains for the (SWR × SWXJ-9)F1 stock by peripubertal administration of dehydroepiandrosterone, an androgen precursor.[2, 3]

The thecal/interstitial compartment is also the source for another potential granulosa cell tumor promotive growth factor, transforming growth factor α. Transforming growth factor α is synthesized in the theca of the normal rat ovary,[16] is an epidermal growth factor–related peptide that binds to the epidermal growth factor receptor, and is implicated in tumors of several types.[17] Normal granulosa cells have a limited number of epidermal growth factor receptors, and epidermal growth factor is a modifier of gonadotropin-stimulated differentiative processes in these cells.[12] The (SWR × SWXJ-9)F1 GC tumor is characterized by elevated epidermal growth factor receptor numbers, with altered binding characteristics, and granulosa cell tumor cells show an enhanced proliferative response to this growth factor.[18] In addition to androgens and epidermal growth factor–like growth factors, other granulosa cell regulatory factors, such as transforming growth factor β, are found in thecal/interstitial cell compartment.[19]

In contrast to preneoplastic follicles, the theca is not typically a prominent feature in either primary or metastatic granulosa cell tumors of adult hosts. This suggests that if the thecal/interstitial compartment does provide a granulosa cell tumor inductive signal(s), granulosa cell tumor cell replication quickly becomes independent of this agent(s). Such a change in granulosa cell tumor cell function could be a critical step in malignant progression, and could involve an autocrine mechanism or a genetic alteration. Throughout granulosa cell tumor development, we observed small clus-

ters of loosely adherent or microfollicular granulosa cell tumor cells entering lymphatic or blood vessels. Once granulosa cell tumor cells acquired the ability to proliferate independently of thecal/interstitial cell product or other endocrine stimulation, such clusters of cells could represent a seeding mechanism for disseminating disease.

The (SWR × SWXJ-9)F1 hybrid mice have the highest incidence of spontaneous granulosa cell tumors yet encountered in our experience with the endocrine-genetic SWR model for granulosa cell tumorigenesis.[4] In addition, the frequency of tumor bilaterality in these hybrid mice was fivefold increased over that of the SWR progenitor strain.[1] This bilaterality of granulosa cell tumors appears unique because in other spontaneous rodent models[6, 7] and in other species including humans,[5] cats, dogs, sheep, cows and horses,[8, 9] granulosa cell tumors are almost always unilateral.

The high incidence, multifocal origin, and frequent bilaterality of granulosa cell tumors in this genetically defined hybrid stock suggest that the combined genome of SWR and SWXJ-9 progenitors results in maximal expression of one or more genes critical for granulosa cell tumor initiation. One gene, granulosa cell tumor susceptibility *(Gct)*, has been identified in the recombinant inbred SWXJ strains and is located on chromosome 4.[3] The (SWR × SWXJ-9)F1 mice are homozygous for the susceptible allele of *Gct*. Heterozygosity, at additional as yet unidentified loci, increases the probability for granulosa cell tumor development. Thus in a stochastic model of tumorigenesis, the (SWR × SWXJ-9)F1 mice already have a primary event encoded within their genetic complement that renders their ovaries more susceptible to subsequent tumorigenic stimuli.

In humans, two subclasses of granulosa cell tumors, juvenile and adult, have been proposed that are based on age of onset, histopathologic features, and disease progression.[5] The granulosa cell tumors found in (SWR × SWXJ-9)F1 mice resemble the human juvenile granulosa cell tumor class in several ways. In both mice and humans the majority of granulosa cell tumors arise before achievement of adult ovarian cyclicity. With respect to histopathologic features, we observed (in 42-day-old and older host mice) examples of patterns of cytology, such as hyperchromic nuclei, frequent mitotic figures, and nuclei without grooves, reported for juvenile granulosa cell tumor class.[5] We occasionally observed Call-Exner–like bodies, typical of the adult granulosa cell tumor class. Thus the predominant histologic features observed in the mouse tumors appeared more related to stage of tumor development than representative of a specific pathologic classification. Finally, with respect to disease progression, comparison is difficult because humans diagnosed with granulosa cell tumors undergo surgical intervention, whereas these mice were left untreated to ascertain malignant potential of primary granulosa cell tumors. Prediction of metastatic behavior for human granulosa cell tumors on the basis of morphologic features of the primary tumor at early stages is difficult.[5] Although the prognosis after surgical removal of the tumorous ovary for the majority of human juvenile granulosa cell tumors is very good, 5% to 10% of patients die within 2 years from widely disseminated metastatic disease.[4] These widely divergent disease outcomes suggest that there may be distinct forms of neoplasia, which cannot be easily distinguished by histologic criteria, within the juvenile granulosa cell tumor subclass. The (SWR × SWXJ-9)F1 granulosa cell tumor resembles the rapidly growing, early metastatic form of juvenile granulosa cell tumor.

In summary, the (SWR × SWXJ-9)F1 stock is characterized by a large percentage of granulosa cell tumors originating within a tightly defined developmental period attendant with puberty. Metastatic progression is significant and occurs during the young adult period. Thus these genetically defined mice provide a powerful tool for investigating mechanisms of granulosa cell tumor initiation, factors influencing primary tumor proliferation and differentiation, and changes underlying malignant disease progression. Insight gained from such studies will improve prognostic accuracy and provide rational bases for devising therapeutic methods of progressive disease management.

We thank Priscilla Jewett and Ann Higgins for technical assistance and Drs. John Shire, Roderick Bronson, and Allan Schroeder for their insightful comments. The Jackson Laboratory is fully accredited by the American Association for Accreditation of Laboratory Animal Care.

Differential diagnosis between complete mole and hydropic abortus by deoxyribonucleic acid fingerprints

Toshikatsu Nobunaga, MD, Chihiro Azuma, MD, DMSci, Tadashi Kimura, MD, Yoshihiro Tokugawa, MD, Masahiko Takemura, MD, Shoji Kamiura, MD, Fumitaka Saji, MD, DMSci, and Osamu Tanizawa, MD, DMSci

Osaka, Japan

We used a new method of deoxyribonucleic acid fingerprint analysis to obtain the differential diagnosis between complete mole and hydropic abortus. This method with a deoxyribonucleic acid minisatellite probe requires only a small amount of tissue sample and peripheral blood, and presents individual specific restriction fragment length polymorphisms (deoxyribonucleic acid "fingerprints") by simultaneous detection of many hypervariable regions (minisatellite regions) widely dispersed in the human genome. Southern blot hybridization showed that in cases of complete mole, all polymorphic fragments were exclusively inherited from the father. Some of the polymorphic bands of paternal deoxyribonucleic acid were not observed in molar deoxyribonucleic acid. However, in the hydropic abortus, the polymorphic fragments could be traced back to its parent. These results indicate that deoxyribonucleic acid fingerprints could distinguish the abnormal fertilization of complete mole (androgenesis) from the normal fertilization of hydropic abortus by identifying the difference in genetic variations between complete mole and hydropic abortus at the deoxyribonucleic acid level. (Am J Obstet Gynecol 1990;163:634-8.)

Key words: DNA fingerprint, minisatellite DNA probe 33.15, complete mole, hydropic abortus

Complete hydatidiform mole is a disease of trophoblasts, the layer of ectodermal tissue that attaches the embryo to the uterus. Although there are wide variations in reports on the incidence of complete mole, this tumor is the most common trophoblastic tumor throughout the world. Recent reports have indicated that the incidence of complete mole is 1 per 1200 pregnancies in United States, 1 per 500 pregnancies in Japan, and 1 per 100 pregnancies in Indonesia.[1-3] In addition to the high morbidity rate, the property of complete mole as a major risk factor to choriocarcinoma has attracted the attention of many gynecologists.[1-4]

This tumor is characterized macroscopically by a grapelike appearance that results from the accumulation of fluid in the mesenchymal core, and microscop-

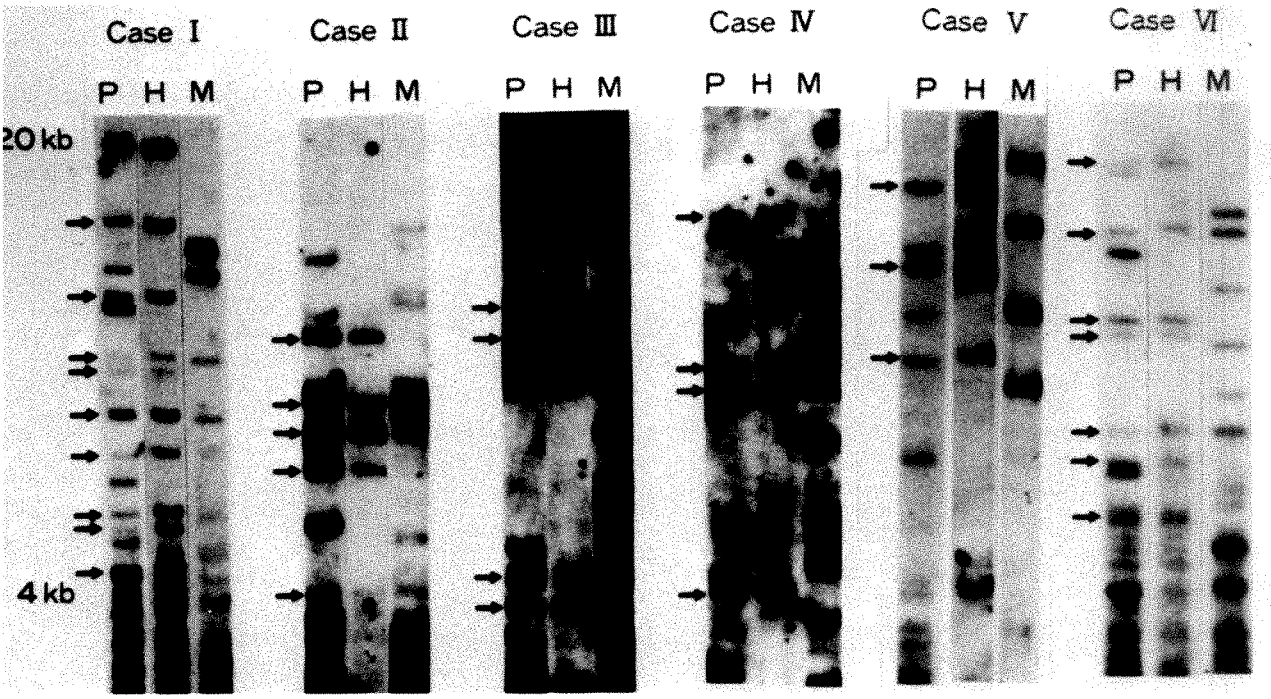

Fig. 1. The DNA fingerprints of six sets (cases I to VI) of hydatidiform molar *(H)*, paternal *(P)*, and maternal *(M)* DNA using the minisatellite DNA probe 33.15. Each polymorphic band in molar tissue can be identified as paternal in origin *(arrows)*, but some of the bands are not detected in molar tissue.

ically by trophoblastic proliferation on the villous surface. Conversely, the placental villi of spontaneous abortion frequently show hydropic change, a cystic formation of villi resembling the vesicles of complete mole. Clinically it is important to discern the hydropic abortus from complete mole because the relative risks of choriocarcinoma associated with molar pregnancy have been estimated to be 2000 to 4000 times higher than those of choriocarcinoma associated with normal pregnancy or aborted pregnancy.[5] The differential diagnosis between complete mole and hydropic abortus is generally obtained on the basis of gross and histologic findings. However, it is sometimes difficult to distinguish blighted ovum with severe hydropic changes from complete mole by histologic examination.[6]

The recent advances of recombinant deoxyribonucleic acid (DNA) technology have made it possible to characterize the genetic variations at the DNA level and revolutionalized human genetic analysis. The most prevailing method of DNA analysis is restriction fragment length polymorphisms, that is, the variation in size of restriction fragments of genomic DNA.[7] We have reported the restriction fragment length polymorphism analysis of complete mole as a new approach for the determination of androgenesis of complete mole, and showed that this method is useful for the study of the pathogenesis of the trophoblastic tumors.[8] We have shown that the differential diagnosis between complete mole and hydropic abortus can be obtained precisely by restriction fragment length polymorphism analysis with the minisatellite DNA probe 33.15, which is capable of presenting individual specific restriction fragment length polymorphisms called DNA fingerprints.[9]

Material and methods

Samples. Six molar tissues and two placental tissues with severe hydropic changes were obtained at the time of therapeutic curettage. The samples were washed repeatedly in cold phosphate-buffered saline solution, pH 7.2, and separated from maternal tissue with a pair of scissors under the dissecting microscope. In each of the six cases of moles and two cases of hydropic abortus, maternal and paternal mononuclear cells from peripheral blood samples were used for DNA extraction. High-molecular-weight DNA was extracted from molar tissues, hydropic placentas, and mononuclear cells of their parents by standard method.

Restriction enzyme digestion and DNA blotting. The extracted high-molecular-weight DNA sample (5 μg each) was digested with endonuclease *Hin*fI at 37° C for 3 hours. The digested samples were electrophoresed through a 20-cm-long 0.6% agarose gel until all DNA fragments <2 kb long had electrophoresed off the gel. After electrophoresis DNA were transferred by blotting to a nitrocellulose filter according to the

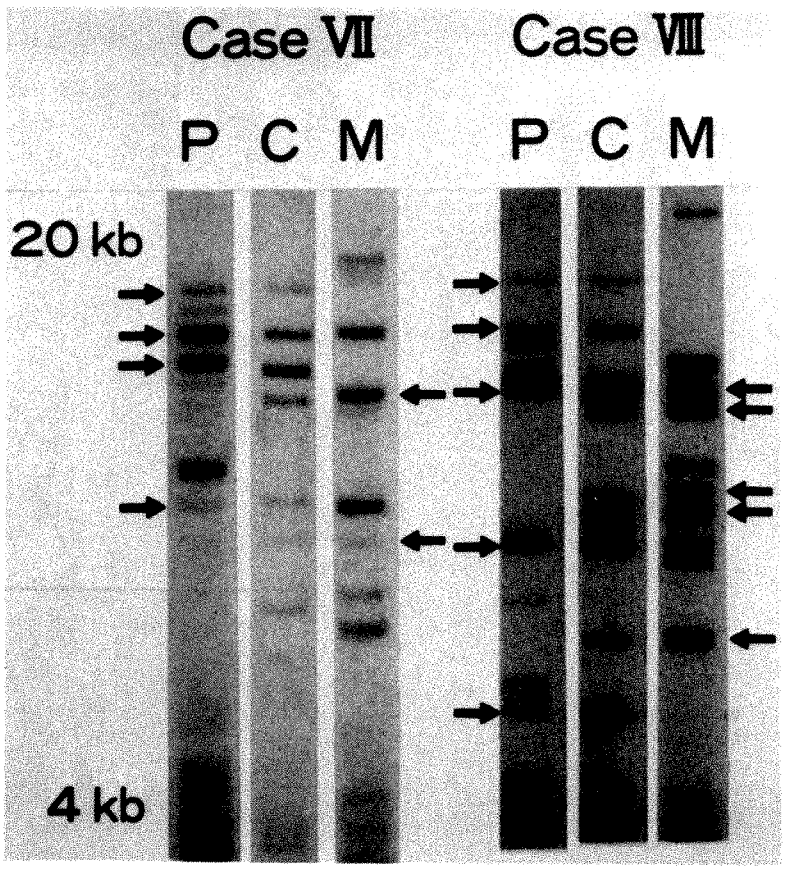

Fig. 2. The DNA fingerprints of two sets (cases VII and VIII) of hydropic chorion *(C)*, paternal *(P)*, and maternal *(M)* DNA using the minisatellite DNA probe 33.15. All bands in hydropic placenta can be traced to either parent *(arrows)*.

method of Southern.[10] The filter was baked in a vacuum oven at 80° C for 3 hours.

Hybridization and autoradiography. DNA probe 33.15, a minisatellite DNA probe, was used for restriction fragment length polymorphism analysis. (The probe was provided by Dr. Alec J. Jeffreys, University of Leicester.) The probe was labeled with phosphate 32α–deoxycytidine triphosphate by multiprime DNA labeling system (Amersham, England) to a specific activity of 1.8×10^9 cpm/μg. The ^{32}P-labeled probe was hybridized to genomic blots at 65° C for 12 hours. The hybridization was performed in Denhardt's solution, 1 mol/L sodium chloride, 50 mmol/L Tris hydrochloride (pH 7.4), 10 mmol/L ethylenediaminetetraacetic acid (EDTA), 0.1% sodium dodecyl sulfate, and 0.1% mg/ml denatured sonicated salmon sperm DNA. The filter was washed once at room temperature in 2× sodium chloride–sodium citrate and twice at 65° C in 1× sodium chloride-sodium citrate, 0.1% sodium dodecyl sulfate for 30 minutes.

Autoradiography was done with Kodak XRP-1 film (Kodak, Rochester, N.Y.) and a Lightning Plus intensifying screen (Dupont, Boston) at −80° C for 48 hours.

Results

Restriction fragment length polymorphism analysis using the minisatellite DNA probe 33.15 was performed on *Hin*fI–digested DNA of molar tissues and their parental mononuclear cells. Fig. 1 shows the profile of restriction fragment length polymorphism band patterns (DNA fingerprint) detected by probe 33.15 of six sets of complete moles and their parents. In the 4 to 20 kb size area, each individual of parents presented 10 to 20 bands that were clearly resolved, and few bands were shared among randomly selected pairs of individuals. Smaller fragments <4 kb long did not present strict individual specificity, probably a result of lower genetic variability of these loci and the fortuitous comigration of unrelated minisatellite fragments. It has been shown that these individual specific fragments >4 kb in length are unintentionally transmitted

from parents to their offspring according to Mendelian law.[9, 11] In the six cases of complete mole, however, all the bands were exclusively inherited from the fathers. Furthermore, some of the polymorphic bands in the paternal DNA fingerprint were not observed in the molar DNA fingerprint. Therefore the restriction fragment length polymorphism band pattern of mole was not identical to that of the paternal one. This phenomenon indicates the androgenetic origin of complete mole that resulted from the fertilization of an anuclear empty ovum by a single sperm that duplicates its haploid chromosomal complement or by two sperms.

In the two cases of hydropic abortus, each polymorphic fragment in the 4 to 20 kb size range of the DNA fingerprint could be traced back to its parent (Fig. 2), which suggests the parental contribution to the genome of hydropic placenta that resulted from normal fertilization.

These results indicate that even though a differential diagnosis between complete mole and hydropic abortus cannot be obtained by histologic examination, because of the severe hydropic changes of a blighted ovum, DNA fingerprint analysis could distinguish the hydropic abortus from complete mole.

Comment

Karyotype analysis has revealed that the karyotype of complete mole shows usually 46,XX, but occasionally it expresses 46,XY. Both sets of chromosomes are derived only from the father.[12] This phenomenon is explained by the fertilization of an "empty" ovum by a single X chromosome bearing sperm that duplicates its chromosomal complement[13] or by two sperms.[14] Conversely, the karyotype of conceptus, even though it presents severe hydropic change, shows 46,XX or 46,XY, and both sets of chromosomes contain parental elements. Theoretically, chromosomal marking can distinguish the hydropic abortus from complete mole. However, the karyotype analysis requires a time-consuming tissue culture (several weeks), and the analysis of chromosome banding patterns requires special techniques. Therefore this method is not suitable for the clinical laboratory. In this study we introduced a newly developed method of DNA fingerprinting to obtaining a differential diagnosis between complete mole and hydropic abortus. All the polymorphic fragments of hydropic abortus could be traced back to either parent; however, in molar tissue all the polymorphic fragments were inherited only from the father, indicating that the method of DNA fingerprinting could distinguish hydropic abortus from complete mole. The DNA fingerprint analysis has many other advantages: (1) It is a simple and more rapid method than karyotype analysis, and the results can be known within a few days. (2) The high-molecular-weight DNA for DNA fingerprint analysis can be easily extracted not only from fresh materials but also from frozen samples. (3) Less than 0.1 gm of tissue or 0.5 ml of peripheral blood can always provide sufficient DNA for analysis, and the extracted DNA can be preserved at 4° C for an extended time. (4) The DNA probe used for the restriction fragment length polymorphism analysis is directed against intranuclear DNA; thus a maternal source of DNA outside the chromosomal DNA (i.e., mitochondrial DNA of maternal origin) is excluded from contamination in this investigation. One problem with this method lies in distinguishing hydropic abortus from partial mole, another major category of hydatidiform mole. The karyotype of partial mole shows triploidy, typically 69,XXX, resulting from the fertilization of a normal haploid ovum by two normal sperms[15]; thus the polymorphic fragments in the DNA fingerprint of partial mole are transmitted from their parents as in normal pregnancy or hydropic abortus. Clinically, however, it is not important to discern hydropic abortus from partial mole because there is increasing evidence that shows that partial mole may not be associated with choriocarcinoma.[16] To the clinician it is essential to distinguish complete mole from hydropic abortus or partial mole. The DNA fingerprint is a more precise and rapid method compared with other conventional methods for the differential diagnosis of trophoblastic tumors. It is expected to contribute to the clinical management of trophoblastic tumors.

Gestational changes in mechanical properties of skinned muscle tissues of human myometrium

Hidetaka Izumi, MD, Jirou Ichihara, MD, Yoshio Uchiumi, MD, and Koichi Shirakawa, MD

Fukuoka, Japan

We developed a technique to obtain very thin myometrial muscle strips that allowed comparison of characteristic features of contraction from the same strip under intact and membrane-permeable ("skinned") conditions. Absolute tension development per unit of cross-sectional area induced by high potassium and oxytocin concentrations in the intact condition, or by Ca^{2+} in the skinned condition, markedly increased in human myometrium at term compared with the nonpregnant state. The maximum tension in skinned strips was 8.3 mN/mm² in nonpregnant strips and 47.5 mN/mm² at term (both obtained at 10 μmol/L Ca^{2+}). The Ca^{2+} sensitivity of the contractile proteins in skinned strips also increased at term compared with the nonpregnant state; the half-maximal response of Ca^{2+} sensitivity was 0.7 μmol/L in the nonpregnant state and 0.3 μmol/L at term. These results suggest that in human myometrium both the amount of contractile proteins and their sensitivity to Ca^{2+} may increase at term compared with the nonpregnant state. (Am J Obstet Gynecol 1990;163:638-47.)

Key words: Human myometrium, smooth muscle, skinned fiber, Ca^{2+} sensitivity, oxytocin

Uterine contractile force for expelling the fetus has been suggested to be related to increased cell volume, a rise in cell numbers or in the amount of contractile proteins in the cell, or to an increase in the efficacy of cell-to-cell connections during gestation, as estimated from biochemical, histochemical, or electrophysiologic evidence.[1, 2] According to current knowledge, calmodulin is likely to be the main Ca^{2+} receptor of the contractile proteins in smooth muscle cells, and the myosin light-chain kinase activated by the Ca^{2+}-calmodulin complex phosphorylates the myosin light chain. Myosin light-chain phosphorylation is essential for the initiation of smooth muscle contraction.[3-5] Both the activity of myosin light-chain kinase and the total amount of calmodulin in the rabbit myometrium increase during the progress of gestation.[6] Therefore the mechanical properties of myometrial cells also may change as gestation progresses. However, it is not yet clear whether these changes also occur in the human myometrium in situ.

Ca^{2+} is thought to play an essential role in contraction in smooth muscles. In myometrial cells, spontaneously generated and agonist-activated contractions are closely related to membrane activity.[2, 7] We and others recently reported that agonist-induced contractions in the rat

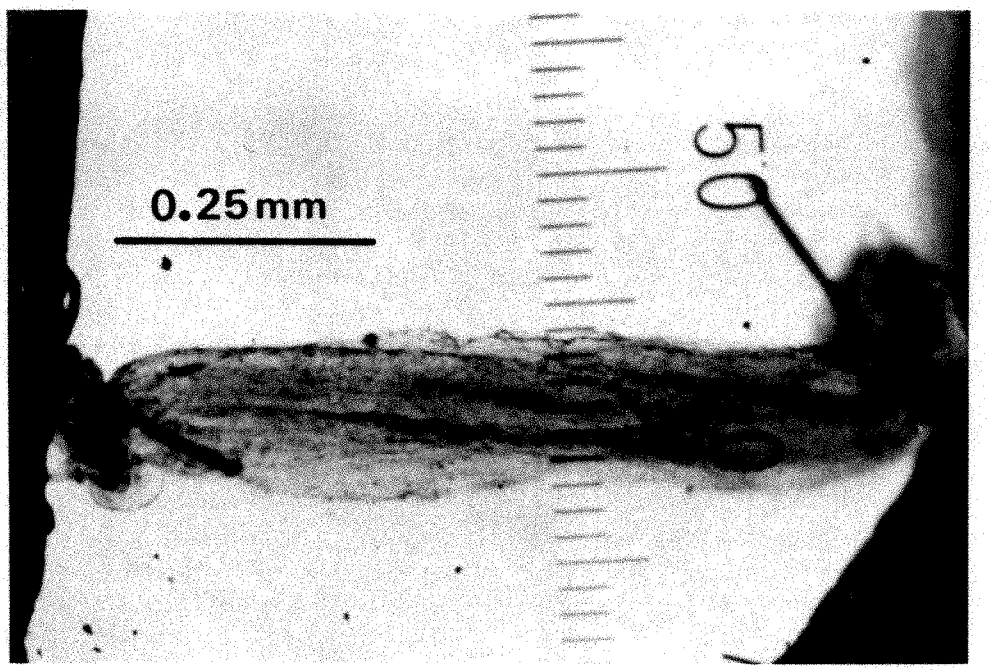

Fig. 1. Low-power light photomicrograph of a muscle fiber bundle of human myometrial strip in the experimental chamber. Small portions of the connecting silk fibers and double-sided Scotch tape are visible at each end. The knot-to-knot length was 0.80 mm, the width 0.11 mm, and the thickness 0.04 mm. Cross-sectional area was estimated to be 3.5×10^{-3} mm^2. This micrograph was taken in the relaxing solution after saponin treatment; temperature was 25° C.

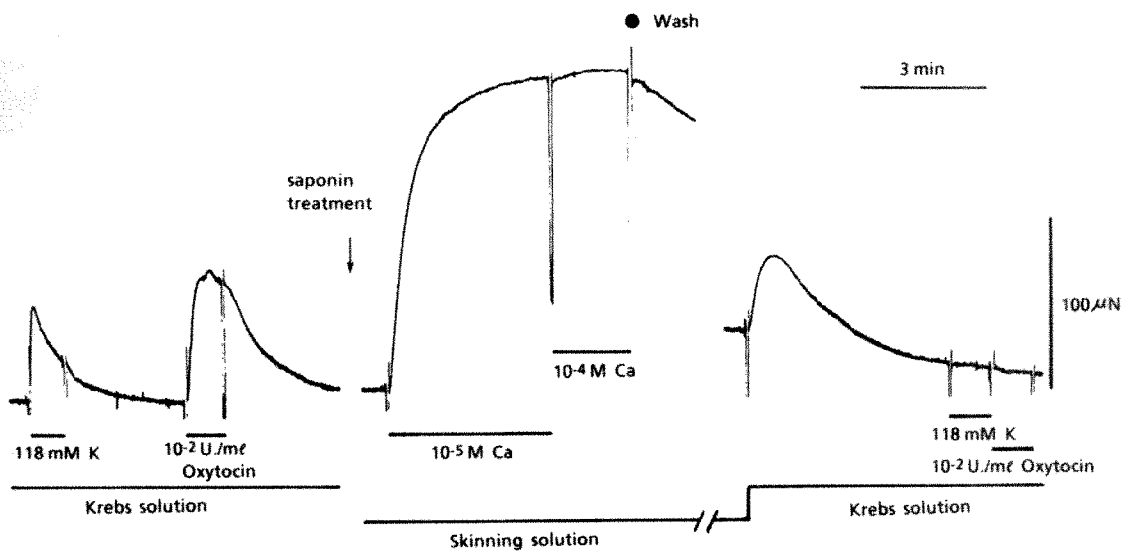

Fig. 2. Records showing criteria for the successful skinning of a muscle fiber strip of the human myometrium. First, 118 mmol/L K^+- and 10^{-2} U/ml oxytocin-induced contractions in the intact condition were recorded, then the bathing solution was replaced with relaxing solution. After saponin treatment contractions were recorded at concentrations of Ca^{2+} of 10^{-5} and 10^{-4} mol/L. Increasing the concentration of free Ca^{2+} to 10^{-4} mol/L did not change the amplitude above that produced by 10^{-5} mol/L. Finally, when the relaxing solution was replaced with modified Krebs solution for 0.5 to 1 hour, neither 118 mmol/L K^+ nor 10^{-2} U/ml oxytocin produced a contraction. When the relaxing solution was changed to the modified Krebs solution, a transient contraction was evoked. Because the modified Krebs solution has no adenosine triphosphate, the tension decay may be a result of a slow adenosine triphosphate diffusion from the strips.

myometrium use both extracellular (Ca^{2+} influx) and intracellular (Ca^{2+} release from storage sites) Ca^{2+}.[8, 9] It is plausible that changes in the contractile machinery occur during the progress of gestation.

In these experiments we attempted to clarify changes in the contractile machinery of human myometrium at term compared with the nonpregnant state. The results are discussed in relation to the gestational changes in Ca^{2+} regulation mechanisms in human myometrial cells.

Material and methods

Material. For the nonpregnant preparations, myometrial tissue was obtained from the anterior wall of the uterine corpus of six nonpregnant women who underwent hysterectomy for benign gynecologic indications (myoma, four cases; endometriosis, two cases). The mean age was 37.6 years (range, 35 to 43 years). For the pregnant at term preparations, small myometrial tissue samples were obtained from the upper incisional edge of the lower uterine segment at the time of term cesarean section with the mother under epidural anesthesia before the administration of the oxytocin (eight parous women were admitted for repeat cesarean section). The mean age was 34.3 years (range, 27 to 37 years). Both preparations were immediately placed in cold, modified Krebs solution and transported to the laboratory. Informed oral consent was obtained from the patients before tissue sampling. Myometrial strips were prepared at room temperature in modified Krebs solution during aeration with 97% oxygen and 3% carbon dioxide. To prepare the muscle strips (0.07 to 0.13 mn in width, 0.04 to 0.06 mm in thickness, and 0.7 to 0.9 mm in length), the connective tissue was carefully removed with the aid of a dissecting microscope.

Recording of mechanical responses. A muscle strip was mounted horizontally in an experimental recording chamber (capacity 0.9 ml). Both ends of the preparation were fixed with pieces of Scotch double-sided adhesive tape (3M Co., St. Paul, Minn.) and isometric tension was recorded with a strain-gauge transducer (U-gauge, Shinko, Tokyo). Width and thickness of the preparations were measured from photomicrographs with a calibrated scale, and the cross-sectional area was calculated assuming an ellipsoidal cross-section as described previously[9, 10] (Fig. 1). The test solution was applied by jetting from one end of the chamber and the solution in the chamber was siphoned from the other end. In intact muscle tissues, the maximum responses evoked by high K^+ concentration or 1×10^{-2} U/ml oxytocin were not affected by propranolol (1×10^{-6} mol/L), phentolamine (1×10^{-7} mol/L), guanethidine (1×10^{-6} mol/L), methysergide (3×10^{-7} mol/L) or mepyramine (1×10^{-6} mol/L). The maximum amplitude of contraction induced by 1×10^{-2} U/ml oxytocin was not modified in the presence of prostaglandin $F_{2\alpha}$ (1×10^{-5} mol/L) or prostaglandin E_2 (1×10^{-5} mol/L).

For the assessment of Ca^{2+} sensitivity, the tissues were skinned with saponin, according to previously described methods.[9, 11] Detailed experimental procedures for skinned muscles are described in Fig. 2. Oxytocin (10^{-2} U/ml), prostaglandin $F_{2\alpha}$ (10^{-5} mol/L), or prostaglandin E_2 (10^{-5} mol/L) had no effect on the amplitude of contraction induced by various concentrations of Ca^{2+} in saponin-treated skinned muscle strips.

The ionic composition of the modified Krebs solution was as follows: Na^+, 137.4 mmol/L; K^+, 5.9 mmol/L; Mg^{2+}, 1.2 mmol/L; Ca^{2+}, 2.6 mmol/L; HCO^{-3}, 15.5 mmol/L; H_2PO^{-4}, 1.2 mmol/L; chlorine, 134.0 mmol/L; and glucose, 11.5 mmol/L. The solution was bubbled with 97% oxygen with 3% carbon dioxide. High K^+ solution (118 mmol/L K^+) was prepared by replacing the sodium chloride with potassium chloride isosmotically; Ca^{2+}-free solution was prepared by the omission of calcium chloride from the solution and the addition of 2 mmol/L ethylene-glycol-bis-(-aminoethylether)-N,N,n′,n′-tetraacetic acid (EGTA). The pH of the solutions was 7.2. The ionic composition of the relaxing solution was: 111 mmol/L K^+-methanesulfonate, 20 mmol/L Tris maleate, 5 mmol/L Mg^{2+}-methanesulfonate, 5 mmol/L adenosine triphosphate (10 mmol/L Na^+ as Na_2ATP) and 4 mmol/L EGTA. The pH was 6.8. Solutions of various Ca^{2+} concentrations were prepared by adding appropriate amounts of Ca^{2+}-methanesulfonate to EGTA. The apparent binding constant of EGTA for Ca^{2+} was considered to be 1×10^6/mol at pH 6.8 and 25° C.[10, 11]

Drugs used in these experiments were as follows: oxytocin (for injection use; Teikoku Zoki), nicardipine (Yamanouchi), prostaglandin $F_{2\alpha}$ (Ono), prostaglandin E_2 (Ono), propranolol hydrochloride (Sigma), phentolamine (Ciba-Geigy), guanethidine sulfate (Ciba-Geigy), mepyramine maleate (May and Baker), methysergide maleate (Sandoz), saponin (ICN), adenosine triphosphate (Boehringer), EGTA (Dozin), and calmodulin (Sigma).

Where appropriate, the results obtained are expressed as the mean ± SEM. The n values represent the number of specimens. The statistical significance of the difference between mean values was assessed by Student's t test, and probability values of $p < 0.05$ were considered significant.

Results

Effects of high K^+ and oxytocin on contractions of intact human myometrial strips. Thin muscle preparations (cross-sectional area between 2.2×10^{-3} mm² and 6.1×10^{-3} mm²) were obtained from human myometrium at two different stages: nonpregnant and the terminal stage of gestation. Strips prepared from either stage did not show any apparent spontaneous mechanical activity. The maximum amplitude of contraction induced by oxytocin was as great as that produced by prostaglandin $F_{2\alpha}$ but larger than that produced by prostaglandin E_2.

When a solution containing 118 mmol/L K^+ was applied, a large phasic contraction, followed by a small

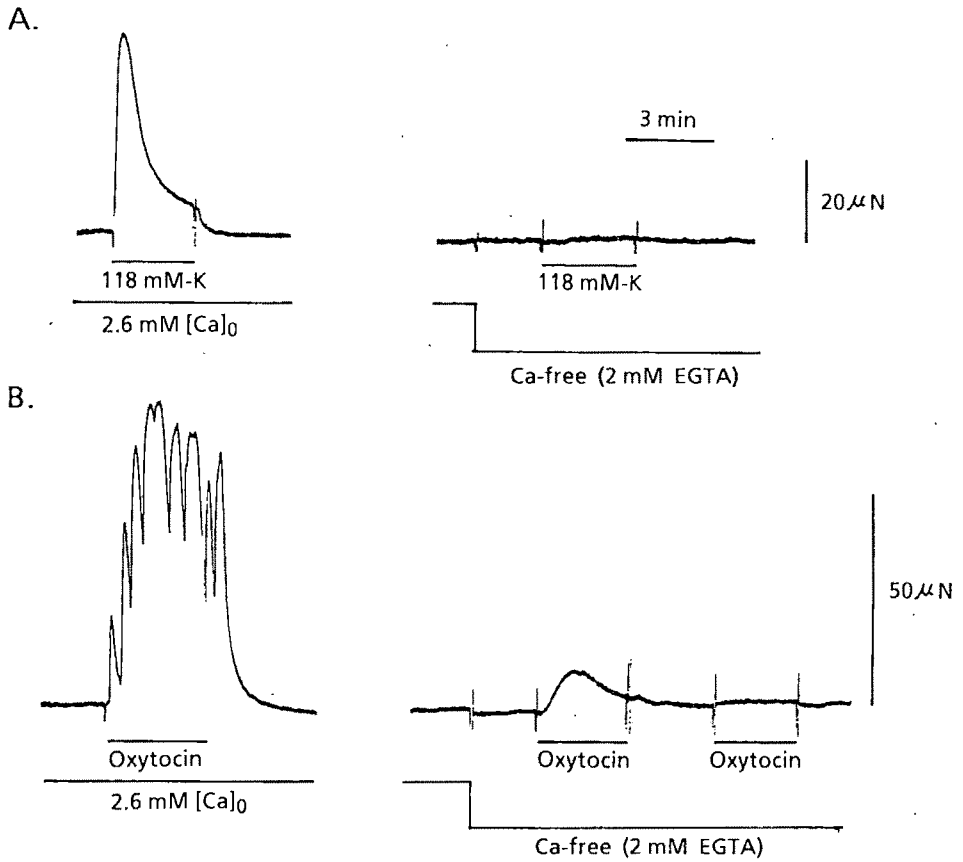

Fig. 4. Effects of **(A)** 118 mmol/L K^+ and, **(B)** 10^{-2} U/ml oxytocin in 2.6 mmol/L Ca^{2+}-containing solution and Ca^{2+}-free (2 mmol/L EGTA containing)—solution in human myometrial strips at term. These results are typical of those from eight experiments.

tonic contraction, was provoked in strips from either stage, and the shape of the contraction was almost the same in the two types of strips. Conversely, oxytocin (>10 mU/ml) induced a monophasic contraction in nonpregnant myometrial strips. However, in the strips taken at term, all concentrations of oxytocin provoked oscillatory contractions, whereas higher concentrations of oxytocin produced a phasic contraction followed by a tonic contraction on which the oscillatory contractions were superimposed (Fig. 3, *A* and *B*). Fig. 3, *C* summarizes the effects of various concentrations of oxytocin on mechanical activity in the strips taken at each stage. In nonpregnant strips the amplitude of contraction induced by 10 mU/ml oxytocin was almost the same as that induced by 118 mmol/L K^+ (0.97 times, $p > 0.1$). However, in strips taken at the terminal stage of gestation, oxytocin (10 mU/ml) produced a larger contraction than 118 mmol/L K^+ (1.51 times, $p < 0.005$). These results indicate that the sensitivity to oxytocin of the human myometrium is greatly enhanced at the end of gestation.

Effects of Ca^{2+}-free solution on contractions of intact myometrial strips induced by high K^+ or oxytocin. In Ca^{2+}-free solution containing 2 mmol/L EGTA, 10 mU/ml oxytocin, but not high K^+ concentration, produced a small transient contraction (without a tonic contraction). However, a subsequent application of oxytocin in Ca^{2+}-free solution produced no contraction (Fig. 4). These results indicate that oxytocin produces contraction via activation of Ca^{2+} influxes and via release of Ca^{2+} from the intracellular Ca^{2+} storage site(s).

Ca^{2+}-induced contraction in skinned muscle strips from human myometrium. To investigate gestational changes in the contractile proteins of human myometrium, we studied Ca^{2+}-induced contractions in chemically skinned muscle strips. To compare the amplitude of contraction in strips in the intact muscle with those of the skinned muscles, the contractions induced by 118 mmol/L K^+ and 10 mU/ml oxytocin were recorded, and the plasma membrane of the muscle strips was hyperpermeabilized by application of saponin (30

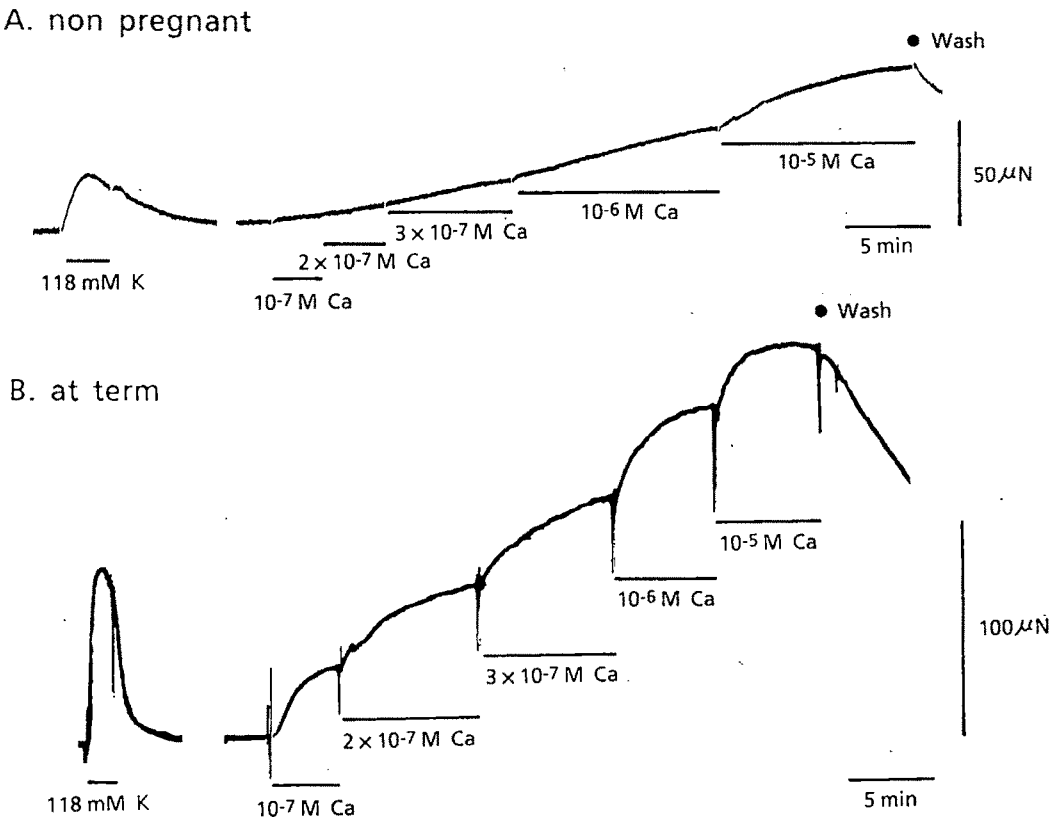

Fig. 5. Effects of various concentrations of Ca^{2+} on mechanical activity in skinned human myometrial strips when nonpregnant **(A)** and at term **(B)**. Before skinning with saponin (30 μg/ml), 118 mmol/L K^+ and 10^{-2} U/ml oxytocin were applied. After skinning the tissues, solutions containing 10^{-7} to 10^{-5} mol/L Ca^{2+} were applied cumulatively. These results are typical of those from six to eight experiments.

μg/ml) for 25 minutes in relaxing solution (thus producing "skinned" muscle strips). To minimize the deterioration of Ca^{2+}-induced contractions, various concentrations of Ca^{2+} were cumulatively applied in a stepwise manner just after the skinning procedure.[10, 11]

Fig. 5 shows the effects of various cumulatively applied concentrations of Ca^{2+} on mechanical activity in skinned strips. In strips prepared from myometrium that was nonpregnant or at term, solutions of over 0.1 μmol/L Ca^{2+} produced contraction; the maximum contraction was obtained by application of 10 μmol/L Ca^{2+}. Greater concentrations of Ca^{2+} (up to 0.1 mmol/L) did not further increase the amplitude. The tension gradually decreased after removal of Ca^{2+}. The maximum amplitude of contraction induced by Ca^{2+} in skinned strips was consistently larger than that induced by high K^+ concentration or oxytocin in intact strips whether from the nonpregnant state or the term stage of gestation ($p < 0.01$).

Fig. 6 shows the plotted data of Ca^{2+}-induced contraction. The median effective dose values were 0.66 ± 0.02 μmol/L Ca^{2+} in nonpregnant strips and 0.28 ± 0.02 μmol/L Ca^{2+} at the terminal stage of gestation ($n = 6$ to 8, mean ± SEM). The pCa tension curve obtained from the term strips was shifted to the left in comparison with that observed for the nonpregnant strips. These results indicate that contractile proteins underwent an increase in Ca^{2+} sensitivity during gestation.

To compare the amplitude of contraction produced in strips taken at the two different stages, the maximum amplitude of contraction was expressed as tension per cross-sectional area (see Methods). The tension induced by 118 mmol/L K^+ or 10 mU/ml oxytocin in strips at the terminal stage of gestation was larger than in nonpregnant strips (4.3 times with use of high K^+ solution and 6.4 times for oxytocin; $p < 0.005$). When the maximum Ca^{2+}-induced tension in skinned strips was compared at the two different stages, the strips at term generated 5.7 times the tension produced by those obtained at the nonpregnant stage ($p < 0.005$) (Fig. 7).

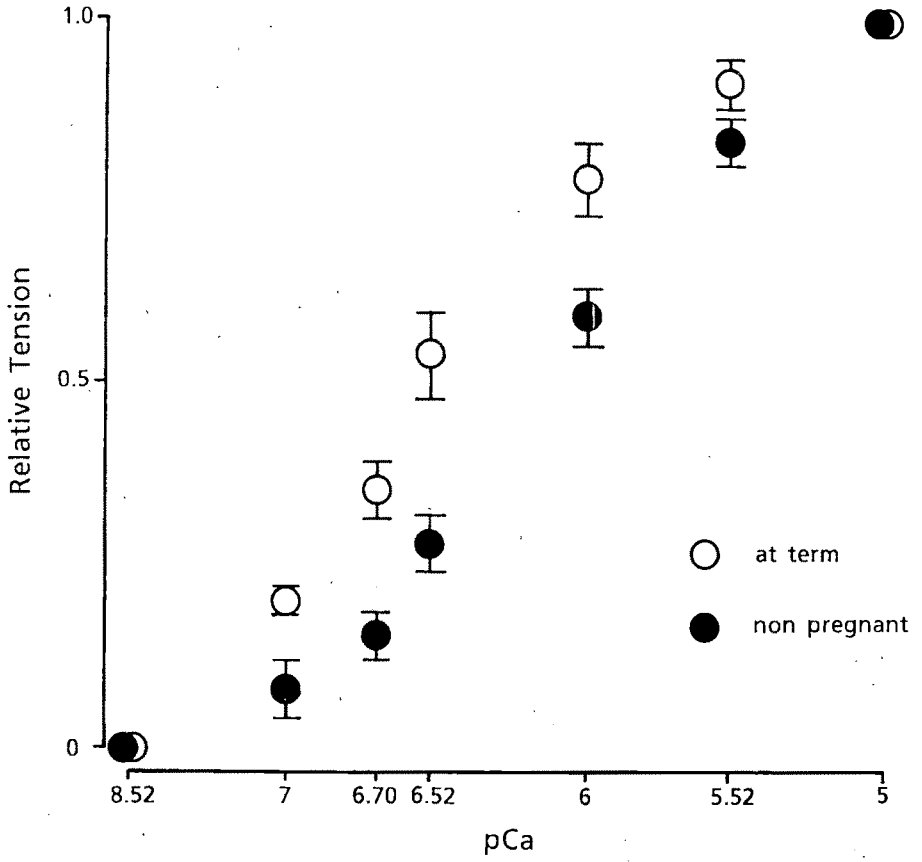

Fig. 6. The pCa-tension relationships observed in skinned human myometrial strips. The contractions are expressed in relation to the size of the contraction induced by 10^{-5} mol/L Ca^{2+} for each state; *solid circles,* nonpregnant; *open circles,* at term. Values represent the means; *vertical bars* indicate SEM, n = six to eight experiments.

The contractions induced by 118 mmol/L K^+ or 10 mU/ml oxytocin in intact strips were compared with the contractions induced by various concentration of Ca^{2+} in the same strips after skinning. The free Ca^{2+} concentrations required to evoke the 118 mmol/L K^+-induced contraction or the 10 mU/ml oxytocin-induced contraction were estimated from the pCa-tension curve for each stage of gestation. The estimated free Ca^{2+} concentrations induced by 118 mmol/L K^+ were 0.35 ± 0.03 μmol/L in the nonpregnant myometrium and 0.22 ± 0.03 μmol/L at term. Those induced by 10 mU/ml oxytocin were 0.33 ± 0.02 μmol/L for the nonpregnant myometrium and 0.29 ± 0.03 μmol/L at term (Fig. 8). These data suggest that the increase in free Ca^{2+} concentration induced by high K^+ or oxytocin in myometrium at term is of lesser magnitude than in the nonpregnant myometrium.

Comment

Our principal findings are as follows: (1) tension per unit of cross-sectional area evoked by high K^+ concentration or oxytocin in living strips, and the maximum Ca^{2+}-induced tension in skinned strips increased during gestation, (2) Ca^{2+} sensitivity of the contractile proteins measured in skinned myometrial strips was increased at the terminal stage of gestation, and (3) the minimum concentration of oxytocin required to produce a contraction was lower in strips from the terminal stage of gestation than in those from the nonpregnant stage.

The absolute tension developed per unit of cross-sectional area evoked by stimulants in intact strips was markedly increased at the end of gestation. The same effect was observed on Ca^{2+}-induced contractions in skinned strips when the intracellular ionic environment was artificially modified. Thus the increase in tension development at the terminal stage of gestation is not caused solely by changes in the plasma membrane ionic permeability (to Na^+, K^+, Ca^{2+}, or Cl^-) or by the increased density or number of oxytocin receptors.

Calmodulin is a Ca^{2+} receptor of contractile proteins, and the Ca^{2+}-calmodulin complex initiates contraction

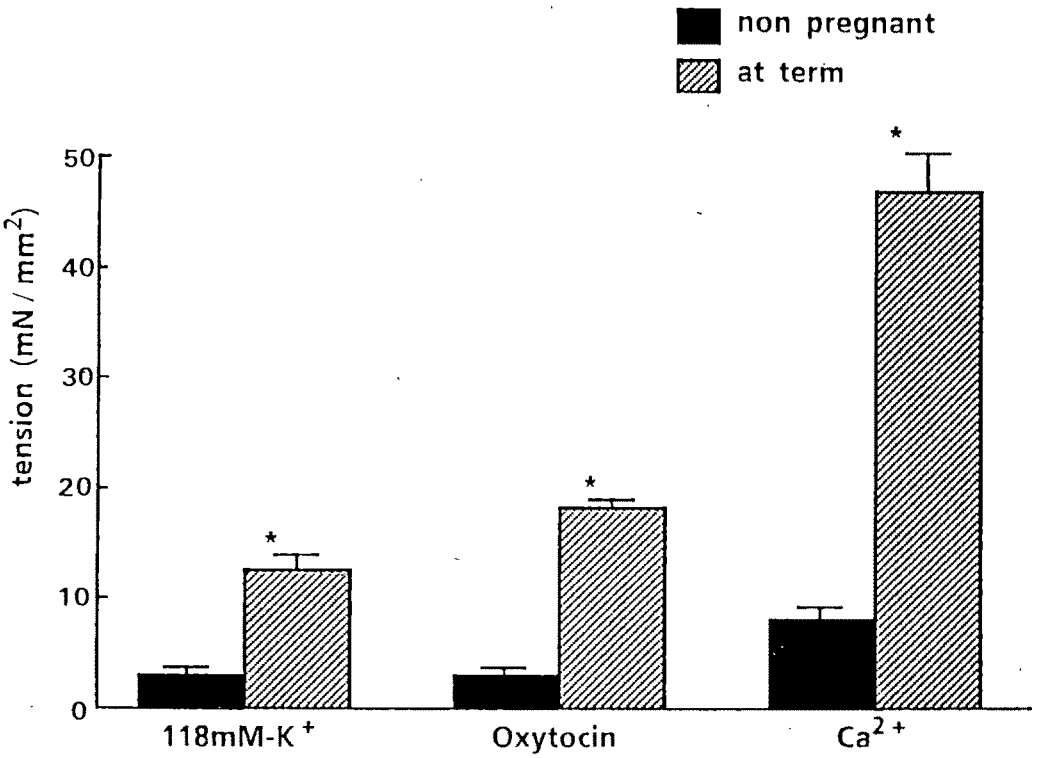

Fig. 7. The tension induced by 118 mmol/L K^+ or by 10^{-2} U/ml oxytocin in intact strips from the nonpregnant myometrium *(solid columns)* and at term *(hatched columns)*. Also shown is the maximum tension induced by Ca^{2+} in skinned strips. The tension is expressed in mN/mm^2. Values are means with bars indicating SEM, n = six to eight experiments. *Asterisks* represent significant differences between mean values for nonpregnant and term states.

by myosin phosphorylation via activation of myosin light-chain kinase in smooth muscle cells.[3-5] Matsui et al.[6] reported that both the amount of calmodulin and the activity of myosin light-chain kinase per milligram of tissue are increased during gestation in the rabbit myometrium. These results suggest that increases both in the amount of contractile proteins and of calmodulin could explain the observed increases in Ca^{2+} sensitivity of the contractile proteins and the maximum Ca^{2+}-induced contraction in skinned strips of human myometrium. However, this needs to be clarified in an intact single cell of the human myometrium.

In these experiments the concentration of oxytocin required to produce the maximum contraction was higher in our myometrial strips than other species. However, the minimum concentration of oxytocin required to produce a contraction in the myometrium at term was much less than in the nonpregnant state. In addition, Edwards et al.[12] reported that oxytocin at low concentration (0.1 mU/ml) increased the frequency of spontaneous contractions and at high concentration (1 mU/ml to 10 mU/ml) induced tonic responses with superimposed small phasic tension. This was not observed on the nonpregnant uterus.

In Ca^{2+}-free solution oxytocin produced only a phasic contraction. Thus Ca^{2+} release from the intracellular storage site(s) may occur in human myometrial strips from the terminal stage of gestation. Recently it was reported that hormones and neurotransmitters synthesize inositol-1,4,5-trisphosphate (IP_3) through hydrolysis of phosphatidyl inositol-4,5-bisphosphate, and that IP_3 releases Ca^{2+} from the sarcoplasmic reticulum.[13] Moreover, IP_3 produces contraction caused by the release of Ca^{2+} in the skinned myometrium of the pregnant rat.[14] In the myometrium the volumes of sarcoplasmic reticulum (possible candidates for the intracellular Ca^{2+} storage sites) increase during gestation.[15] We previously reported that the acetylcholine-induced contraction in Ca^{2+}-free solution was enhanced in rat myometrium with the progress of gestation.[9] It has been shown that oxytocin in the myometrium generates IP_3 and that IP_3 causes calcium release from uterine microsoma.[16,17] Nevertheless, IP_3-sensitive Ca^{2+} release mechanisms may contribute to the increased sensitivity to oxytocin of the mechanical activity of myometrial tissue at the terminal stage of gestation, although such an increase could result from an increase in the number of oxytocin receptors.

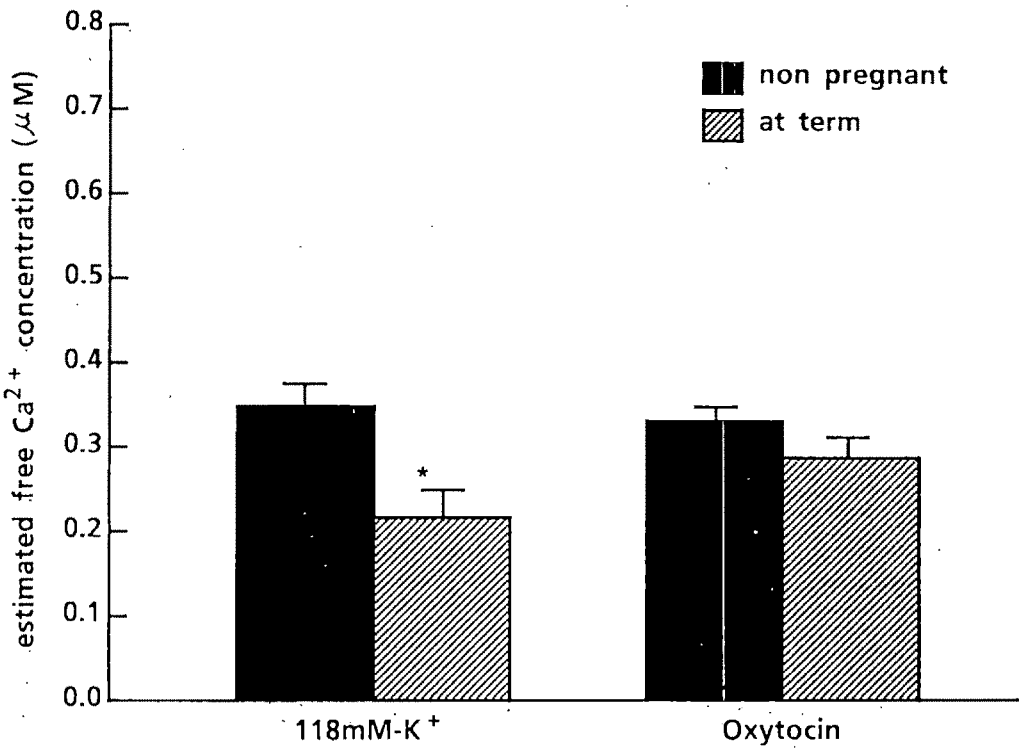

Fig. 8. The estimated free Ca^{2+} concentration required for the contraction induced by 118 mmol/L K^+ or 10^{-2} U/ml oxytocin in human myometrial strips taken from nonpregnant subjects *(solid columns)* and at term *(hatched columns)*. Values represent the means; *vertical bars* indicate SEM, n = six to eight experiments. *Asterisks* denote significant differences between means for nonpregnant and term states.

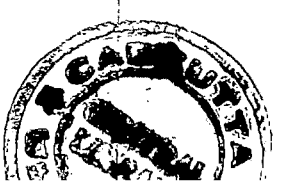
Our data suggest that the increase in the free Ca^{2+} concentration induced by oxytocin or high K^+ concentration is of lesser magnitude at term than in the nonpregnant human myometrium. Thus a smaller amount of free Ca^{2+} can produce a larger contraction in the myometrium as gestation progresses. Because the Ca^{2+} sensitivity of contractile proteins is higher in strips at the terminal stage of gestation, it may be that Ca^{2+}-handling mechanisms in the cell (such as Ca^{2+} reuptake to the storage sites or Ca^{2+}-extrusion mechanisms via the Ca^{2+} pump or Na^+-Ca^{2+} exchange on the plasma membrane) more effectively regulate Ca^{2+} concentration as gestation progresses. As a consequence cellular Ca^{2+} concentration may be maintained at a lower level and may more rapidly decline after stimulation. Because the amplitude of contraction induced by oxytocin was larger than that induced by high K^+ concentration at the terminal stage of gestation, the voltage-independent Ca^{2+} influx and Ca^{2+} release mechanism from the storage site may become more important at this time.



In conclusion, in the human myometrium at term the maximum amplitude of contraction induced by oxytocin is greatly increased compared with the nonpregnant state. This may be predominantly a result of increases in both the amount of its contractile proteins and its Ca^{2+} sensitivity. Roles that may be played by the Ca^{2+} storage sites in the oxytocin-induced contraction are also suggested.

We thank Prof. Hirosi Kuriyama and Dr. Takeo Itoh, Department of Pharmacology, Faculty of Medicine, Kyushu University, and Dr. Janice M. Marshall, Department of Physiology, School of Medicine, Birmingham University, for editorial comments and assistance.

Alteration of 24-hour rhythms in myometrial activity in the chronically catheterized pregnant rhesus monkey after a 6-hour shift in the light-dark cycle

Jorge P. Figueroa, MD, PhD, M. Barbera O. M. Honnebier, MD, Susan Jenkins, and Peter W. Nathanielsz, MD, PhD

Ithaca, New York

We determined the effect of a 6-hour phase shift in the light-dark cycle on the 24-hour rhythm of myometrial activity with 15 chronically catheterized pregnant rhesus monkeys during the last third of gestation. Monkeys were housed indoors in constant temperature on a 14-hour-light/10-hour-dark photoperiod in two groups based on the time the lights were turned on (group A lights on at 6 AM and group B lights on at midnight). The power spectra were calculated for periods of 512 readings (1.138 hours) starting at the time the lights were turned on for continuous periods of 25.03 hours of data showing well-developed contraction-type activity at any time during that period. The power spectra data for contractures and contractions were analyzed separately from myometrial electromyographic data. During the 14 hours of light, myometrial activity was primarily composed of contractures. In all experimental animals the switch from contractures to contractions occurred around the time the lights were turned off. The proportion of contraction-type activity in each 1.138-hour analysis interval expressed as a percentage of the total contraction power for the whole 25.03-hour analysis period for all monkeys increased around the time the lights were turned off in both groups. The increase in contractions was observed 12 to 15 hours after the lights were turned on. No systematic change in the proportion of contracture activity was observed. Peak contraction activity was 22.6 ± 0.60 hours (16.6 hours after lights on), and was at 18.3 ± 1.4 hours (18.31 hours after lights on) in groups A and B, respectively. This difference was statistically significant (22.6 ± 0.6 vs 18.3 ± 1.4 hours, $p < 0.05$). Seven of eight monkeys in group A and six of seven in group B had switched from contractures to contractions before lights were turned off. We have confirmed a 24-hour rhythm in myometrial activity in the pregnant rhesus monkey and provided new evidence to support the endogenous nature of this rhythm and its direct relationship to the light-dark cycle (AM J OBSTET GYNECOL 1990;163:648-54.)

Key words: Myometrial activity, circadian, monkey, phase shift, pregnancy

In nonhuman primates the existence of a 24-hour rhythm in uterine activity is well documented.[1-5] However, data from different laboratories differ in the time of maximal uterine activity. Harbert[2] reported a diurnal rhythm in the chaired pregnant rhesus monkey in which maximum integrated intrauterine pressure occurred between 2:08 PM and 6:33 PM, when the lights were turned off at 4 PM. In a second report, maximal integrated intrauterine pressure occurred between 10:16 AM and 12:54 AM during the 36 hours before delivery, also with the time of lights off at 4 PM.[3] In contrast, Ducsay et al.[4] reported a nocturnal maximum in the rhythm in intrauterine pressure in the chaired pregnant rhesus monkey. Maximum hourly integrated intrauterine pressure, analyzed as the ratio between the total area under the intrauterine pressure curve per hour divided by the overall mean for the 24-hour recording period, occurred at midnight. In these studies the lights were turned off at 11 PM. Electromyographic recordings of uterine activity at three different times of the day in chaired cynomolgus monkeys showed that under conditions of natural lighting, the frequency of electromyographic events was higher between 8 PM and 9 PM compared with 4 AM to 5 AM and noon to 1 PM.[6] The first report on a 24-hour rhythm in myometrial activity in chaired pregnant rhesus monkeys with continuous myometrial electromyographic recording described a nocturnal increase in the frequency of contraction-type myometrial activity.

Contractions, when observed, occurred around the time lights were turned off (7 PM) with the highest amplitude at midnight.[5]

In all studies to date in the pregnant monkey, regardless of whether the maximum uterine activity was present during the hours of light or darkness, increased activity was always present around the time that lights were turned off. Catecholamines,[1] estrogens,[7, 8] oxytocin,[9, 10] and dehydroepiandrosterone sulfate[7] are all putative factors capable of driving the 24-hour rhythm in uterine activity, either directly or indirectly. We have been particularly interested in this transition period during which contracture-type myometrial activity changes to contractions. In the pregnant rhesus monkey this change occurs under several conditions, such as after operation,[6] before delivery,[6] during food withdrawal,[11] and when estrogen synthesis is increased by infusion of androstenedione into the mother.[8] In this study we sought to determine the effect of a 6-hour shift in the light-dark cycle on the change from contractures to contractions.

Material and methods

Fifteen pregnant rhesus monkeys of known gestational age were acclimated to the laboratory conditions as previously described.[5, 11, 12] Before the pregnancy under study, the animals usually were housed indoors with a 12 hour light/12 hour dark light-dark cycle with lights on at 6 AM at the primate center. In our laboratory they were housed in rooms with controlled light cycles 14:10 hours light-dark for at least 30 days before operation. The light intensity changed from 484 lux during the lights-on period to 5 lux during the dark period. No animal had the photoperiod changed or shifted during the stay in the laboratory. Food provided was Purina 5045 Monkey Chow (Ralston Purina, St. Louis) and fresh fruits presented to the animals every day at 8 AM (biscuits and fruit) and at 1 PM (fruit only). Monkeys had access to water during the entire experimental period. At operation monkeys ranged from 83 to 112 days gestational age. All animals were instrumented with techniques described previously in detail.[5, 11, 12] Briefly, with the animals under halothane anesthesia, catheters were placed in the maternal dorsal aorta and inferior vena cava via the femoral artery and vein. In each animal two pairs of myometrial electromyographic leads were sewn into the myometrium on the anterior wall of the uterus. Two catheters made of Tygon microbore tubing (Norton Performance Plastics, Akron, Ohio) (inner diameter, 1.27 mm; outer diameter, 2.29 mm) with a side hole 1 cm from the tip, were placed 3 to 6 cm within the amniotic cavity. A small prefabricated Tygon retaining collar around the catheter was located just within the uterus. A Yellow Spring 44032 thermistor (Yellow Springs Instrument Co., Yellow Springs, Ohio) was sutured to the anterior uterine wall. The day of operation was considered day 0. All animals but one received 75 μg buprenorphine for analgesia twice a day for the first two postoperative days. All animals were maintained on a 14-hour light/10-hour-darkness regimen. The animals were studied in two groups based on the onset of the 14 hours of light in their light-dark cycle. Animals in group A were housed in rooms with lights on at 6 AM and off at 8 PM from the day they arrived at the laboratory. Because we wished to conduct further experiments in which we would sample mother and fetus around the time lights were turned off, we changed the lighting regimen by 6 hours so the time the lights were turned off was more convenient for laboratory personnel. Animals in group B were housed in rooms with lights on at midnight and off at 2 PM from the day they arrived at the laboratory.

Recording of myometrial electromyogram and data storage. The uterine electromyogram was recorded from multistranded bipolar stainless steel wires (Cooner AS 632, Cooner Wire Co., Chatsworth, Calif.) implanted 3 to 5 mm apart on at least two sites of the myometrium.[5, 12] Acquisition of the myometrial electromyogram was performed with a computer-based data acquisition system.[13] Briefly, the electromyographic signals were sampled at 32 Hz and the average value over 8 seconds was digitized and stored as one data point reading with a time signal.

Determination of power spectrum frequency windows that characterize contractions and contractures. Fast Fourier Transform and power spectrum analysis were performed on the digitized electromyographic data with an Asyst 2.0 program.[14] We have previously demonstrated that the 0.01 to 0.11 cycles/min frequency window represents a component of uterine activity that has a low frequency (i.e., greater than one epoch of activity every 9 minutes) and correlated well with instances in which only contracture-type activity was present. The second frequency window (0.2 to 0.8 cycles/min) represents the contraction-type uterine activity. To quantify the changes in activity in each of the windows, we integrated the area under each window and defined total contraction power and total contracture power. If the area in the 0.2 to 0.8 cycles/min frequency window increases at any given period, it means that the animal had more contraction-type uterine activity than the previous period.[14]

Data analysis. Each analysis period began when the lights were turned on. Uterine electromyographic data were selected from individual monkeys with continuous periods of 25.03 hours of uninterrupted data showing well-developed contraction-type activity at any time during that period. Monkeys were 2 to 30 days after operation and 94 to 125 days of gestation on the days the recordings were used for analysis. Data were avail-

able on 2 days from thirteen and on 1 day in two animals (Table I). The power spectra for frequencies between 0.01 and 0.8 cycles/min were calculated for periods of 512 8-second readings (1.138 hours) starting at the time the lights were turned on. Twenty-two data points were obtained, covering a continuous period of 25.03 hours. The power spectra data for contractures and contractions were analyzed separately. Each analysis interval (1.138 hours) was expressed as a fraction of the total activity during the total analysis period (25.03 hours).

Statistical analysis. Data for the area of increased activity were fitted to a normal distribution in individual animals. Mean time at peak activity and its confidence interval in either group were computed. The two-sample *t* test was used to compare mean time at peak activity between the two groups. To determine whether a monkey had already switched from contractures to contractions before the lights were turned off, the mean time of the peaks minus 1.96 SDs (2.5th percentile) was calculated in each animal. If the time value for the 2.5th percentile occurred earlier than the time lights went off (8 PM for group A or 2 PM for group B), the monkey's contraction activity was considered to have anticipated the time lights were turned off. In those animals with two days of suitable recording the data were averaged for that animal before analysis. Data throughout are presented as the mean ± SD.

Results

During the 14 hours of light, uterine activity was mostly primarily of contractures. In all experimental animals the change from contractures to contractions occurred around the time the lights were turned off. Data shown in Figs. 1 to 4 focus on the two time windows 6 PM to 10:33 PM (group A) and noon to 5:33 PM (group B). These windows include the time the light went off in each group. Figs. 1 and 2 show the raw electromyographic and power spectrum analysis data for one animal from each group. In monkey no. 8 housed in a 14-hour-light/10-hour-dark photoperiod with lights off at 8 PM, uterine activity between 6 PM and 10:33 PM showed a switch from contractures to contractions in both the raw electromyographic and the power spectra for frequencies between 0.01 and 0.8 cycles/min (Fig. 1). In contrast, monkey no. 9 housed in a 14-hour-light/10-hour-dark photoperiod with lights off at 2 PM showed only contracture-type activity

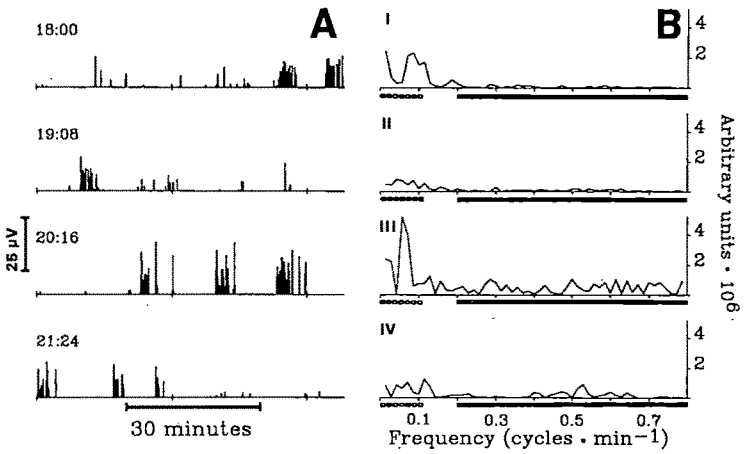

Fig. 2. A, Continuous electromyographic recording data for 4.33 hours (clock time indicated) and **B,** power spectrum for the data in **A** at *(I)* 6 PM to 7:08 PM (18:00 to 19:08); *(II)* 7:08 PM to 8:16 PM (19:08 to 20:16); *(III)* 8:16 PM to 9:24 PM (20:16 to 21:24); and *(IV)* 9:24 PM to 10:32 PM (21:24 to 22:32) in a pregnant rhesus monkey at 115 days' gestation housed in a room with lights off at 2 PM. *Heavy solid line,* Contraction window; *broken line,* contracture window.

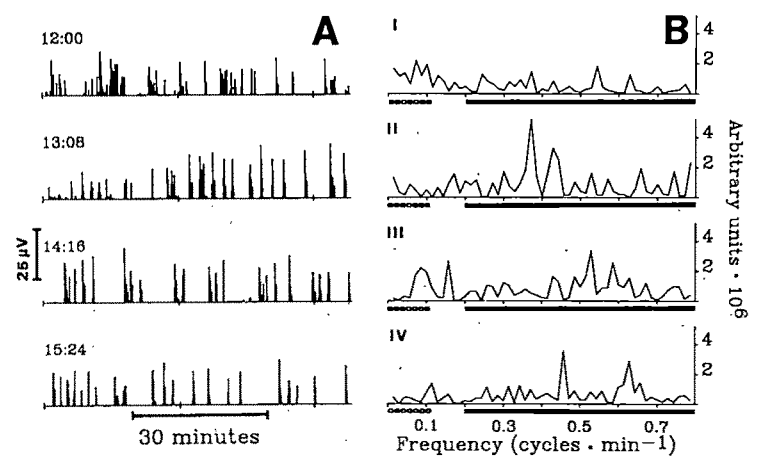

Fig. 3. A, Continuous electromyographic recording data for 4.33 hours (clock time indicated) and **B,** power spectrum for the data in **A** at *(I)* noon to 1:08 PM (12:00 to 13:08); *(II)* 1:08 PM to 2:16 PM (13:08 to 14:16); *(III)* 2:16 PM to 3:24 PM (14:16 to 15:24); and *(IV)* 3:24 PM to 4:32 PM (15:24 to 16:32) in a pregnant rhesus monkey at 115 days' gestation housed in a room with lights off at 2 PM. *Heavy solid line,* Contraction window; *broken line,* contracture window.

in the 6 PM to 10:33 PM time window (Fig. 2). In monkey no. 9 uterine activity between noon and 4:33 PM showed a switch from contractures to contractions (Fig. 3), whereas monkey no. 8 showed only contracture-type activity in the noon to 4:33 PM time window (Fig. 4.) in both the raw electromyographic data and the power spectrum.

The proportion of contraction-type activity in each 1.138-hour analysis interval expressed as a percentage of the total contraction power for the entire 25.03-hour analysis period for all monkeys increased around the time the lights went off. The increase was observed 12 to 15 hours after the lights were turned on for both group A (Fig. 5, *A*) and group B (Fig. 6, *A*). No systemic change in the proportion of contracture activity throughout the 25.03-hour period was observed in either group (Fig. 5, *B* and 6, *B*).

Table II shows the mean time of peak activity calculated as the peak value of the fitted normal distribution on individual animals. Mean time of peak activity for animals in group A was at 22.55 ± 0.60 hour (clock time) that corresponds to 16.56 hour after lights went on. The confidence interval was 22.04 to 23.06. Mean time of peak activity for animals in group B was at 18.31 ± 1.39 hour (clock time) that corresponds to 18.31 hours after lights went on. The confidence in-

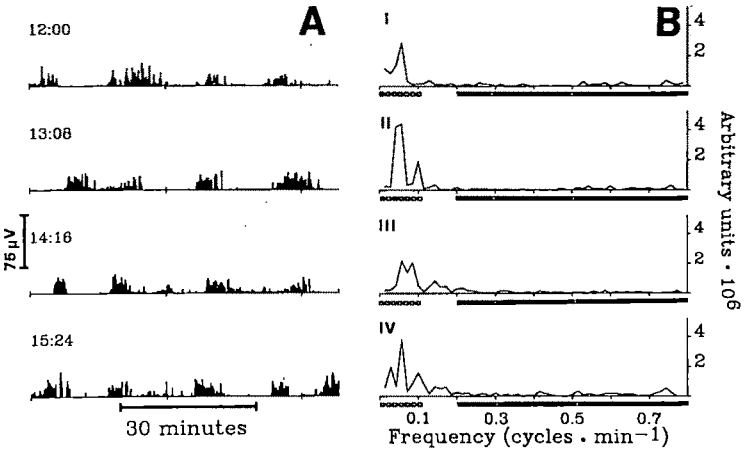

Fig. 4. A, Continuous electromyographic recording data for 4.33 hours (clock time indicated) and **B,** power spectrum for the data in **A** at *(I)* noon to 1:08 PM (12:00 to 13:08); *(II)* 1:08 PM to 2:16 PM (13:08 to 14:16); *(III)* 2:16 PM to 3:24 PM (14:16 to 15:24); and *(IV)* 3:24 PM to 4:32 PM (15:24 to 16:32) in a pregnant rhesus monkey at 110 days' gestation housed in a room with lights off at 8 PM. *Heavy solid line,* Contraction window; *broken line,* contracture window.

terval was 16.88 to 19.41. The mean time at peak activity between groups A and B was statistically different (22.55 ± 0.60 versus 18.31 ± 1.39 hours; $p < 0.05$, two-sample t test), when clock time is used, and they are not different (16.56 ± 0.6 versus 18.31 ± 1.39) when time relative to lights on is used.

As shown in Table II the majority of animals in both groups had a 2.5th percentile time value less than the time at which lights were turned off. Seven of eight monkeys started their increased activity before 8 PM in group A and six of seven displayed contractions before 2 PM in group B. Thus most animals had already switched from contractures to contractions before the lights were turned off.

Comment

Mammalian biologic rhythms are driven by an endogenous oscillator that is constantly adjusted to the environment by entrainment based on external cues.

The goal of the study was to determine the effect of a 6-hour shift in the light/dark cycle on the 24-hour rhythm of myometrial activity. The results enable us to exclude feeding time and cleaning time as possible exogenous conditioning stimuli driving this rhythm. Feeding and cleaning occurred at the same clock time irrespective of whether animals belonged to group A and group B. However, the change from contractures to contractions occurred at the same time in relation to the time lights were turned off.

Our data suggest that the 24-hour myometrial rhythm is entrained rather than driven by the change in light intensity (from lights on to off) because no animal showed a change from contractures to contractions at the exact time lights were turned off. Thirteen of the fifteen animals studied showed a switch from contractures to contractions that anticipated the time the lights went off. Anticipation is a characteristic of endogenous rhythms when entrained by an external cue. Environmental temperature does not affect the period of circadian rhythms, but it can act as a zeitgeber under natural conditions.[15] Temperature is kept constant under our laboratory conditions and can therefore be ruled out as a zeitgeber in our studies.

These data confirm previous reports from our laboratory and others that the myometrium in the pregnant rhesus monkey is most active during the early hours of darkness. Although different methodologies were used by the different research groups, all studies show the highest activity around the time lights were turned off. Some activity always occurred before the lights went off.

With an oxytocin antagonist we have shown that oxytocin plays a role in the switch from contractures to contractions under certain conditions.[10] However, the exact mechanism by which oxytocin may operate has not been determined. A 24-hour rhythm in oxytocin plasma concentration is one possible mechanism that may explain a 24-hour rhythm in myometrial activity.

Changes in the sensitivity of the myometrium to oxytocin throughout the 24-hour day is another possible pathway by which oxytocin may determine the rhythm in myometrial activity. We have shown that the myometrium is more sensitive to oxytocin when administered in the early hours of darkness in pregnant monkeys at 121 to 142 days' gestation housed in a 14-hours-light/10-hours-dark cycle.[9]

The involvement of steroids in the control of myometrial activity has been suggested by several studies.[4, 7, 8] Increased maternal plasma estrogen concentrations induced by food withdrawal[7] or 48-hour

intravenous administration of the estrogen precursor 4-androstenedione[8] is associated with the appearance of contractions during the dark period. Fetal plasma dehydroepiandrosterone sulfate concentration is highest at the time of increased myometrial activity.[16] Whether dehydroepiandrosterone truly drives the rhythm or whether plasma concentration changes are purely coincidental has not been established. Fetal dehydroepiandrosterone could affect myometrial activity by providing a source of estrogen precursors to the placenta. Plasma catecholamines have also been suggested to play an important role in the regulation of the 24-hour rhythm in myometrial activity. Harbert and Zuspan[1] have shown a correlation between urinary catecholamine excretion and increased myometrial activity in the nonpregnant monkey. In contrast, no correlation between plasma or amniotic catecholamine concentrations and the cycles of myometrial activity was found in the pregnant rhesus monkey late in gestation (Ducsay CA. Personal communication).

In conclusion, we have confirmed the presence of a 24-hour rhythm in myometrial activity in the pregnant rhesus monkey and provided new evidence to support the endogenous nature of this rhythm and the direct relationship to the light-dark cycle. Future studies involving constant illumination are required to determine the exact role and nature of the cues provided by the light-dark cycle.

We thank Karen Moore for help with the manuscript and Julie Martel for her advice in the statistical analysis.

Nifedipine enhances the cardiac toxicity of magnesium sulfate in the isolated perfused Sprague-Dawley rat heart

John M. Thorp, Jr., MD, F. J. Spielman, MD, Fidel A. Valea, MD, F. G. Payne, MD, R. A. Mueller, MD, and Robert C. Cefalo, MD

Chapel Hill, North Carolina

Magnesium sulfate is commonly used in tocolytic regimens and as prophylaxis against seizures. Nifedipine may be used simultaneously in either situation. With the isolated perfused rat heart model (Sprague-Dawley rats), we investigated the effects of these agents on cardiac function. Whereas each agent alone depressed cardiac performance, the two drugs together had maximal depressive effects on the heart. (AM J OBSTET GYNECOL 1990;163:655-6.)

Key words: Nifedipine, magnesium sulfate, tocolysis

Preterm labor and preeclampsia complicate a significant number of pregnancies. Magnesium sulfate, commonly used as a tocolytic agent, is the agent of choice for seizure prophylaxis in the preeclamptic patient. Recently nifedipine, which is a calcium channel agonist, has been added to tocolytic[1] and antihypertensive[2] regimens. Occasionally a patient is simultaneously exposed to magnesium sulfate and nifedipine. Each agent alone is known to have a depressive effect on myocardial function.[3,4] We investigated the interaction of magnesium sulfate and nifedipine in the isolated perfused rat heart.

Methods

This project was approved by the Committee on Animal Research at the University of North Carolina. All care and procedures were within committee guidelines. Thirty Sprague-Dawley rats were anticoagulated with 1000 units of heparin intraperitoneally and anesthesized with ether. The heart of each rat was then rapidly excised, arrested in ice saline solution (0.9%), and attached to a modified Langendorff apparatus. The isolated hearts were perfused with Krebs-Henseleit solution. The solution was aerated with 95% oxygen and 5% carbon dioxide. The perfusate entering and surrounding the heart was warmed by a water-jacketed system to 37° C.

A miniature latex balloon-tipped catheter filled with saline solution (0.9%) was inserted into the left ventricle through the mitral valve to measure cardiac dynamics. Left ventricular systolic pressure was continuously measured. Left ventricular end-diastolic pressure was maintained at 6 mm Hg. Contractility (dP/dt) was determined from the slope of the left ventricular pressure waveform. Atrial and ventricular surface electrodes were placed and heart rate was also recorded. Myocardial cells are viable for at least 90 minutes in Krebs-Henseleit solution.

The hearts were randomized into three groups after 15 minutes of stabilization in the Krebs-Henseleit solution. A set of baseline measurements were obtained. At that time the 10 hearts in group 1 had the magnesium concentration increased from 2.4 mEq/L to 6.4 mEq/L, group 2 had nifedipine added to the perfusate at a rate of 2 ng/min, and group 3 had the magnesium concentration increased to 6.4 mEq/L and nifedipine added. After 10 minutes in the new solution another set of measurements were obtained.

Mean values were obtained from each group at the first and second observations. Means were compared with a Student t test and an analysis of variance where appropriate; $p < 0.05$ was considered significant.

Results

Baseline heart rate, left ventricular systolic pressure, and contractility did not differ between the three groups. The addition of magnesium in group 1 significantly reduced heart rate ($p < 0.03$), left ventricular systolic pressure ($p < 0.0001$), and contractility ($p < 0.00002$). Group 2 had an insignificant decline in mean heart rate and significant diminution of left ventricular systolic pressure ($p < 0.00002$) and contractility ($p < 0.000001$). The hearts in group 3 showed significant declines in heart rate ($p < 0.02$), left ventricular systolic pressure ($p < 0.000001$), and contractility ($p < 0.000001$) (Table I). Overall changes between groups were compared by calculation of the percent

Table II. Percent change in cardiovascular parameters after intervention (mean ± SD)

	Group 1	*Group 2*	*Group 3*
Heart rate	−17 ± 16	−4 ± 7	−18 ± 15
Left ventricular systolic pressure	−35 ± 8	−37 ± 10	−56 ± 12
Contractility	−46 ± 14	−51 ± 12	−73 ± 8

of change in each measurement after drug administration (Table II). The combination of nifedipine and magnesium sulfate produced a larger decrease in left ventricular systolic pressure than did either agent alone ($p < 0.001$). The combination of the two agents also produced a greater percent of decrease in contractility than that of either magnesium sulfate or nifedipine alone ($p < 0.001$).

Comment

Both magnesium sulfate and nifedipine given alone depressed left ventricular systolic pressure and contractility within this model. Nifedipine seemed to reduce heart rate less than did magnesium sulfate. Combining the two agents resulted in more depression of left ventricular systolic pressure and contractility compared with either drug alone. In the modified Langendorff apparatus, nifedipine does potentiate the depressive effects of magnesium sulfate.

Overlack et al. observed a depressive effect on blood pressure when these two agents were combined. The Overlack study found that animals receiving oral supplements of magnesium showed an increased hypotensive effect when given nifedipine.[5]

A recent case report is supportive of the concept that magnesium potentiates the cardiac depressive effects of nifedipine. Waisman et al. reported on two patients who had magnesium infused for preeclampsia while receiving oral nifedipine; both patients had marked hypotension.[6] A similar case on our service in a gravid woman who underwent tocolysis with each agent prompted us to initiate this study.

Nifedipine and magnesium sulfate were potent cardiovascular depressants when combined in this particular model. The isolated Langendorff preparation is without vascular and neural reflexes and attenuation of the depressive effects of these agents may occur in the intact animal when compensatory mechanisms are present. However, we urge the clinician who considers combined use of these agents to proceed with caution.

Effect of intravaginal application of prostaglandin E_2 gel on the mechanical properties of the ovine cervix uteri at term

James R. Owiny, PhD, and Reginald J. Fitzpatrick, PhD
Liverpool, England

The extensibility ("creep" or strain per minute) and the stretch modulus (stress per unit strain) of strips of cervical tissue were measured in vitro. Intravaginal application of prostaglandin E_2 gel led to a fourfold increase in the extensibility (mean ± SE, 15.45 ± 0.26 versus 4.23 ± 0.86 min^{-1}; $p < 0.05$) and a twofold reduction in the stretch modulus (mean ± SE, 0.66 ± 0.03 versus 1.28 ± 0.12 $N \cdot mm^2$; $p < 0.0005$). This marked increase in the degree of softening occurred in the absence of an increase in uterine activity or changes in plasma progesterone concentrations. (Am J Obstet Gynecol 1990;163:657-60.)

Key words: Cervix, extensibility, stretch modulus, softening, prostaglandin E_2

Parturition requires a soft distensible cervix to allow expulsion of the fetus. Cervical ripening is essential if dilatation is to be achieved without damage to the maternal soft tissues or to the fetus. Failure of the cervix to soften and subsequently dilate is an important cause of dystocia in sheep, as well as in human beings. However, there are anatomic differences. For example, the ovine cervix bears characteristic annular folds that virtually obliterate the lumen.

A variety of systems have been developed to measure changes in the physical properties of the cervix, including static loading of isolated cervical rings to measure extensibility,[1] intracervical balloons to measure compliance in vivo,[2-4] and tensile tests (dynamic loading) to determine stretch modulus of cervical strips.[5-8]

Parturition in sheep is preceded by a sharp rise in plasma prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) concentration,[9] which it has been suggested plays an important role in cervical softening.[10, 11] Administration of a prostaglandin synthetase inhibitor at term[8] or during labor[12] inhibits cervical softening in the sheep. There is growing evidence of a direct involvement of $PGF_{2\alpha}$ and prostaglandin E_2 (PGE_2) in cervical ripening in late pregnancy.[10, 11, 13] In human beings PGE_2 is widely used to promote clinical ripening of the unfavorable cervix.[14] The ovine cervix is capable of endogenous production of prostaglandins with the rate of production increasing during late pregnancy to reach a maximum at term,[15] and this may provide a normal mechanism of local control of cervical function.

The present investigation was designed to study objectively the direct effect of intravaginal application of PGE_2 on ovine cervical softening at term.

Material and methods

Precisely date-mated, purebred Welsh mountain ewes ($n = 10$) from a closed flock (modal gestational length = 147 days) were used. At all times procedures for the care and use of the animals conformed to the standards approved by the University of Liverpool.

Around day 130 of pregnancy, one maternal jugular vein was conventionally catheterized. At laparotomy, under halothane anesthesia, an open-tipped polyvinylchloride catheter (1.0 mm inner diameter, 2.0 mm outer diameter, Portex, England) was introduced aseptically into one allantoic sac, anchored to the uterine wall with closure sutures, then exteriorized to the flank and terminated with a three-way tap for subsequent connection to a pressure transducer. Procaine penicillin G 1.25 gm and dihydrostreptomycin 1.25 gm (Streptopen, Pitman-Moore, United Kingdom) were given intramuscularly postoperatively only once. Jugular catheters were flushed daily with heparinized (50 $U \cdot ml^{-1}$) sterile saline solution (0.9% sodium chloride). Studies were designed to end on day 140 or 145 after mating. Ewes were killed by stunning and exsanguination, and the cervix was dissected out with the use of minimum traction.

Uterine activity was monitored by connecting the open-tipped allantoic sac catheters to a physiologic pressure transducer (Bell and Howell, United Kingdom) recording on a four-channel recorder (Devices, United Kingdon). Before the start of treatment, jugular blood samples were collected daily for 2 to 3 days, then every 4 to 6 hours throughout the treatment period. Plasma concentrations of progesterone were measured

by radioimmunoassay.[16] The sensitivity of this assay was 6.0 pg · ml^{-1}, with intraassay and interassay coefficients of variance of 9.5% and 12.5%, respectively.

For intravaginal administration of PGE_2 we used Prostin vaginal gel (Upjohn, United Kingdom) containing 1 mg dinoprost in a sterile prepacked syringe designed for use in women. The packs were stored at 4° C until use. The syringe nozzle was extended 2 cm to facilitate deposition of gel at the external cervical os. Gel was administered every 8 hours times three doses commencing day 139 (2 mg) or 144 (1 mg) ($n = 5$). Gestational age–matched ewes ($n = 5$) in which the syringe was inserted and removed at corresponding times to treated animals were used as controls.

Extensibility

*Creep testing.*Strips approximately 3 mm wide were taken from the dense connective tissue layer of the wall of the cervix and the thickness of the wall was measured microscopically as previously described.[8] The strips were held vertically by clamps (10 mm apart) in aerated (20% oxygen and 5% carbon dioxide) physiologic saline solution in an organ bath at 39° C and equilibrated for 10 minutes before longitudinally loading. A total of three similar sized strips per animals, one each from the uterine, middle, and vaginal regions of the cervix, were tested.

Each strip, effectively 10 mm long and 3 mm wide, was subjected to a static load of 0.5 N and consequential tissue extension was recorded over a period of 1 hour with a precalibrated linear displacement tracking transducer (RDP LVDT type D5/1000, RDP Electronics, United Kingdom). The transducer signal was amplified by a D7M transducer amplifier (RDP Electronics) and fed to a potentiometric recorder (Servoscribe, Smiths, United Kingdom). After initial rapid extension to its true length, each strip extended linearly with time. A straight line was fitted along this linear portion of the extension-time tracing and extrapolated to time 0. From this the initial length (L_0), the length at 1 hour (L_{60}), and the slope of the curve (K) ($K = (L_{60} - L_0)/60$) were obtained. The creep rate (extensibility), calculated with the formula $((K/L_0) \times 10{,}000)$,[5] is a measure of extension per unit length per unit time after application of a load. An increase in creep implies softening of the tissue.

Tensile testing. Tensile testing was performed as previously described.[8] Briefly, nine strips from each cervix were cyclically stretched and relaxed, at 5 mm · min^{-1}, between zero tension and 1 N, in an engineer's tensile testing machine (T5002, J. J. Lloyd Instruments, Southampton, England). The relationship of length to tension was automatically recorded on an XY-Plotter (J. J. Lloyd). A straight line was drawn along the linear portion of the extension-tension plot to determine the length at zero load (L_0). The following parameters were recorded or calculated: cross-sectional area (CSA), length at 1 N (L_{1N}), stress at 1 N (1N/CSA), strain $((L_{1N} - L_0)/L_0)$ and stretch modulus (stress/strain). Stretch modulus is derived from stress divided by strain. The lower the stretch modulus, the easier it is to stretch the tissue (softer). Stress represents tension per unit unstressed cross-sectional area after application of a known force. Strain expresses the increase in length after loading as a fraction of the original length of the specimen.

A one-way analysis of variance was performed on the data with an SPSSX 21 program on an IBM 3081 computer. Because there was no difference ($p < 0.05$) between the responses on different days (140 or 145) or at different doses of PGE_2, the data were pooled.

Results

The results (mean ± SE) of the mechanical tests performed on strips of cervical tissue are shown in Tables I and II. Intravaginal application of PGE_2 gel led to a fourfold increase in the creep rate ($p < 0.05$) and a twofold reduction in the stretch modulus ($p < 0.005$). There was a variation in the creep rate and stretch modulus along the cervix with the uterine end being most extensible.

Recorded uterine activity was negligible in the control and treated sheep: PGE_2 treatment did not stimulate uterine activity. No significant ($p < 0.05$) differences were observed in plasma progesterone concentration (mean ± SE) between the control and treatment groups either before treatment (13.0 ± 5.72 versus 10.4 ± 3.61 ng · ml^{-1}) or after treatment (12.8 ± 5.11 versus 9.8 ± 4.49 ng · ml^{-1}).

Comment

We used two methods to measure changes in the physical properties of the ovine cervix uteri after intravaginal application of PGE_2 gel. The two methods yielded similar results. Our methods allow us to compare cervical strips of a precise size and length thus minimizing variations as a result of differences in the tissue size. Multiple sampling from each cervix allows comparison of different regions of the cervix. Cervical rings in vitro have been used to measure changes in the extensibility[13] of the ovine cervix. In our experience the large size of the ovine cervix and the presence of thick annular bands of wall tissue make this technique unsuitable in the sheep because of the difficulty in preparing rings of even width and because application of traction to large rings in a consistent manner is difficult.[2, 3] Intracervical balloons have also been used in intact sheep,[3] allowing repeated compliance measurements in the same animal. However, the introduction of the balloons itself induces a transient increase in

Table I. Extensibility (creep or strain per minute) of strips of cervical tissue from control and PGE_2-treated sheep on day 140 or 145 of pregnancy

Treatment	*No. of strips*	*L_0 (mm)*	*L_{60} (mm)*	*K ($mm \cdot min^{-1}$)*	*Creep*
Control	15	12.50 ± 0.20	12.70 ± 0.25	0.016 ± 0.011	4.23 ± 0.86
PGE_2	15	15.40 ± 0.94	16.70 ± 0.70	0.024 ± 0.002	15.71 ± 2.11

Table II. The mean (±SE) stretch modulus (Newton · mm^{-2}) of strips of cervical tissue taken from control and PGE_2-treated sheep on day 140 or 145 of pregnancy

Treatment	*No. of strips*	*L_0 (mm)*	*L_{IN} (mm)*	*Slope (Newton · mm^{-1})*	*Stretch modulus*
Control	45	11.85 ± 0.45	13.20 ± 0.60	0.82 ± 0.10	1.28 ± 0.12
PGE_2	45	13.05 ± 0.35	15.05 ± 0.25	0.56 ± 0.03	0.66 ± 0.03

compliance[2] (i.e., it affects the factor it is trying to measure). Furthermore, such balloons must be placed between defined annular rings of the ovine cervix to permit comparisons between animals, but there is no reliable way to ascertain and maintain precise position.

We used our in vitro system to study the effect of intravaginal administration of PGE_2 on cervical softening. A 1.0 mg dose was chosen on the basis of extrapolation from human data.[17] Moreover, we wanted to avoid the risk of inducing contractions.[18] Intravaginal application of PGE_2 led to a marked reduction in the stretch modulus and a dramatic increase in the extensibility of ovine cervical tissue. This occurred in the absence of any significant increase in uterine activity or of change in progesterone status, suggesting local action of the hormone, which agreed with the observations of Ledger, Ellwood, and Taylor.[13] Stys et al[3] used much larger doses of PGE_2 (30 mg, compared with 3 to 6 mg in our study) and reported a tenfold increase in compliance after 20 hours. However, the regimen of Stys et al resulted in clinical labor in three of eight ewes and suggests that uterine contractions were probably initiated not only in these three but also in the other five ewes. Under such circumstances it is difficult to separate the direct prostaglandin effects on cervical softening from those as a result of uterine contractions. Our observation provides evidence for direct action of PGE_2 on softening of the ovine cervix.

We did not find any difference between the response of the sheep to PGE_2 at day 140 and 145, which suggests that the ovine cervix is responsive to the softening effect of PGE_2 by day 140 of pregnancy (i.e., a week before term). This is interesting because this response occurs before the major maternal steroid endocrine changes to which cervical softening has hitherto been attributed.

The gradation in softening along the cervix confirms our earlier report.[8] The reason for the variation is not very clear, but could be related to the distribution of collagen in the cervix. The connective tissue in the cervix is such that the uterine end has the least amount of collagen.[19, 20] Because locally administered PGE_2 is known to influence collagen and proteoglycan metabolism,[17, 21] areas with less collagen could conceivably soften faster. The variability in extensibility of the cervix seen in our study support this suggestion.

Ovine cervical tissue may be less sensitive to PGE_2 than the human cervix, as indicated by the ability of the low doses (2 to 5 mg) per vaginum or (0.5 to 1 mg) intracervically to induce within 12 to 16 hours marked improvement in the cervical state in women at term.[14, 17, 18, 21] There is need for more clinical trials in sheep of PGE_2 gel given per vaginum as a means to induce cervical softening.

We are grateful to Dr. T. W. How of the Department of Biomechanics and Medical Physics, University of Liverpool, for advice. Progesterone antibody was provided by Dr. H. Dobson and Prostin gel by Upjohn, United Kingdom, to whom we express our thanks.

Effects of clonidine on breathing movements and electrocortical activity in the fetal lamb

Owen S. Bamford, PhD, Robert L. Hawkins, BS, and Carlos E. Blanco, MD
Baltimore, Maryland

Clonidine is a recommended antihypertensive for use during pregnancy, although little is known of its fetal effects. This study examines the effects of clonidine on breathing and sleep-state cycling in fetal lambs. Clonidine was infused into a fetal lateral ventricle for up to 24 hours at 128 to 135 days' gestation. Control infusions of artificial cerebrospinal fluid had no effect. Clonidine infusion significantly reduced the incidence and episode duration of fetal breathing for the duration of the infusion period. Cycling of electrocortical activity became irregular and rapid, and the incidence of high-voltage electrocortical activity (equivalent to quiet sleep) was reduced. Fetal heart rate decreased but arterial pressure was unaffected. After infusion the breathing incidence and episode duration both increased significantly compared with control, with continuous high-amplitude breathing for several hours, whereas the incidence of high-voltage electrocortical activity remained low. Because lung development is promoted by fetal breathing, long-term use of clonidine during pregnancy could slow lung development by reducing fetal breathing activity. (AM J OBSTET GYNECOL 1990;163:661-8.)

Key words: Clonidine, fetal breathing, electrocortical activity, lung development

The α_2-adrenergic agonist clonidine is used extensively as an antihypertensive agent and has been recommended for use during pregnancy.[1] Although it has no teratogenic effects or acute toxicity, the possibility of more subtle developmental effects on the fetus has not been studied.

In adults clonidine reduces arterial pressure by acting at inhibitory presynaptic α_2-adrenergic receptors on noradrenergic neurones. This causes hyperpolarization and inhibition of firing[2-4] and leads to a reduction in sympathetic outflow and a decrease in arterial pressure. Other effects include sedation and hypothermia. Although these effects of clonidine are well known, the fetal effects of clonidine have attracted little attention. Intravascular injections of 10 μg clonidine caused an immediate arrest of fetal breathing,[5] although clonidine had no consistent effect on breathing postnatally.[6] The α_2-adrenergic antagonist idazoxan blocked the actions of clonidine, thus confirming its α_2-adrenergic action, although when given alone idazoxan had little effect on fetal breathing; presumably the α_2-adrenergic receptors were not tonically active, and thus their blockade made no difference under normal conditions. Clonidine injections also caused an immediate onset of high-voltage electrocortical activity. Breathing in the fetal lamb is normally suppressed in high-voltage electrocortical activity, but apnea and the shift to high-voltage were shown to be independently mediated since both still occurred after complete brainstem transection.

This evidence suggested that in the fetus noradrenergic facilitatory tone is required to maintain breathing, perhaps via α_1 receptors, and could be blocked by activating α_2-adrenergic receptors either exogenously with clonidine or by an endogenous neurotransmitter, probably noradrenaline. However, we examined only short-term acute effects of systemic injections of these substances and the responses seen could have been nonspecific effects of a transient high plasma concentrations.

To address this possibility and to study the effects of maintained high central concentrations of clonidine we infused clonidine into chronically prepared fetal lambs in utero for periods of up to 24 hours. Because prolonged intravascular infusions of diffusible drugs such as clonidine are likely to produce unpredictable indirect effects on the fetus via changes in the maternal circulation, the agents were administered via an indwelling cannula to a fetal lateral cerebral ventricle for periods up to 24 hours while breathing, nuchal electromyogram, electrocortical activity, arterial pressure, heart rate, and arterial blood gases were recorded.

Table I. Effect of lateral ventricle infusion of cerebrospinal fluid on incidence and episode duration of fetal breathing and electrocortical activity

	Control	*Infusion*	*Postinfusion*
Incidence of high-voltage electrocortical activity (min/hr)	24.7 ± 3.5	22.4 ± 5.8	25.5 ± 2.1
Incidence of breathing (min/hr)	30.0 ± 4.8	29.9 ± 5.5	26.2 ± 5.1
Duration of high-voltage electrical activity episodes (min)	12.1 ± 3.2	11.1 ± 2.9	12.7 ± 2.7
Duration of breathing episodes (min)	13.8 ± 4.0	14.1 ± 3.2	12.9 ± 3.2

All comparisons between control, infusion, and postinfusion values were not significant by ranked-pairs test.

Material and methods

Experiments were performed on a total of 15 fetal lambs prepared for chronic recording using methods based on those of Boddy et al.[7] All procedures and protocols were approved by the institutional animal care and use committee. Pregnant Dorset cross ewes at between 120 and 125 days' gestation were anesthetized with intravenous Pentothal, intubated, and ventilated with oxygen and nitrous oxide 2:1 with 2% halothane. Following normal sterile methods, pairs of stainless steel wire recording electrodes were implanted in the fetal diaphragm, nuchal extensor muscle, and parietal cortex. Vinyl catheters (1 mm inner diameter) were placed in a fetal carotid artery and jugular vein and in the trachea. A fourth catheter ended in the amniotic fluid to act as a pressure reference. A lateral ventricle cannula was placed using a method based on that described by Gluckman and Parsons.[8] An acrylic guide tube was anchored to the skull at 7 mm anterior and 7 mm lateral to bregma with screws and cyanoacrylate glue. A saline-solution–filled cannula made from a 21-gauge hypodermic needle bent at right angles was introduced through the guide until it entered a lateral ventricle as shown by the fall in the saline solution column. The cannula was then glued in place in the guide. Vinyl tubing (0.25 mm inner diameter × 1 m) was attached to the exposed end of the cannula via an adapter tube and secured with cyanoacrylate glue. Dead space of catheter and cannula combined was about 100 μl. The uterus was closed in two layers and catheters and electrodes were exteriorized through a flank incision. Recovery from anesthesia was rapid and the ewes usually stood and fed within an hour of skin closure.

Three days were allowed to elapse from the time of operation before any experiments were performed. An infusion rate of 33 μl/hr was used throughout the study. Drugs were made up in artificial cerebrospinal fluid, adjusted if necessary to pH 6.5 to 7 with carbon dioxide, and sterilized by passage through a 0.22 μm filter. Clonidine was made up at 250 μg/ml and infused at 33 μl/hr (dose rate of 8.3 μg/hr). Preliminary studies indicate that clonidine is stable in solution with no apparent change in potency over several days. In control studies artificial cerebrospinal fluid was infused at the same rate. (See Appendix for composition.) Fetal electrocortical activity, integrated diaphragm and nuchal electromyograms, tracheal and arterial pressures, and heart rate were recorded continuously on Grass polygraphs.

Data were analyzed from the chart recordings manually. For each preparation steady-state measurements were made of the 10 hours before infusion started ("control"), the infusion period starting 4 hours from the start of infusion and continuing to the end ("infusion"), and the 10-hour period starting with the end of the infusion period ("postinfusion"). Mean heart rates and arterial pressures were measured from the traces twice hourly during control, infusion, and postinfusion periods. In each consecutive 2-hour epoch of these periods, the incidence of fetal breathing and high-voltage electrocortical activity were measured in minutes per hour, and the duration of each episode of breathing and high-voltage electrocortical activity measured. No attempt was made to quantify either low- or intermediate-voltage electrocortical activity. All data were entered into spreadsheets (Lotus 1-2-3) for collation, plotting, and statistical analysis. Blood gas samples were obtained during control, infusion, and postinfusion steady-state conditions.

Frequency distributions of some of the data, particularly breathing incidence, were truncated by zero and were therefore clearly nonnormal. Such data cannot be treated by standard parametric statistics and were therefore tested with a nonparametric test (Wilcoxon for unpaired and ranked-pairs test for paired data), and medians are used in these cases instead of means.

Results

Artificial cerebrospinal fluid infusions. Recordings from 11 infusions of artificial cerebrospinal fluid in 11 preparations were analyzed. There were no significant differences between values for control, infusion, and postinfusion on breathing or electrocortical activity (Table I). No effects of infusion on heart rate, arterial

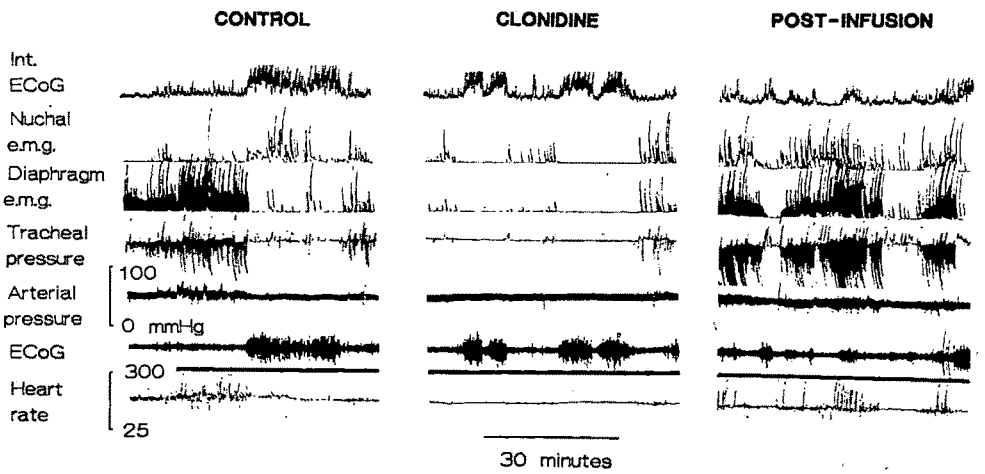

Fig. 1. Typical recordings from a 128-day fetal lamb before, during, and after infusion of clonidine via intraventricular catheter at 9 μg/hr. Vertical and horizontal ordinates apply to all three panels. During clonidine infusion both heart rate and blood pressure show low variability, and diaphragm and nuchal activity are reduced. After infusion episodes of intense diaphragm and nuchal activity occur together and the incidence of high-voltage electrocortical activity remains low compared with control.

Table II. Fetal ascending aortic pH and blood gases under control conditions, during central clonidine infusions, and during recovery

	pH	Pco_2 *(mm Hg)*	Po_2 *(mm Hg)*	*n*
Control	7.443 ± 0.081	42.99 ± 5.29	23.61 ± 4.41	22
Clonidine	7.442 ± 0.061	41.50 ± 4.92	27.15 ± 4.52	7
Recovery	7.395 ± 0.040	43.25 ± 5.39	25.4 ± 4.47	11

*None of the experimental values were significantly different from corresponding control values.

pressure, or nuchal activity were detectable by inspection.

Clonidine infusions. Twenty-one infusions of clonidine at 9 μg/hr were given to 10 fetal lambs at 125 to 135 days' gestation for periods ranging from 7 to 24 hours (mean, 15.6 hours). Blood gas levels were not significantly affected by the infusions (Table II). After steady conditions had been established (maximum of 4 hours from start of infusion), infusion duration had no detectable effect and data for the remaining infusion period were pooled. Fig. 1 shows a comparison between recordings of breathing, electrocortical activity and nuchal activity, heart rate, and blood pressure in a fetal lamb under control conditions and during clonidine infusions. The reduction in electromyographic activity and increased rate of electrocortical activity cycling during clonidine infusion is clear. Both during and after infusion, nuchal and diaphragm electromyographic activity tended to occur together, whereas they were mutually exclusive in control conditions. There was increased breathing and nuchal activity during the postinfusion period. Heart rate was reduced and appeared less variable during infusion. Fig. 2 shows typical changes in incidences (*A*) and episode durations (*B*) for high-voltage electrocortical activity and breathing during a 20-hour infusion.

Breathing. Changes in the incidence (minutes per hour) and mean episode duration (minutes) of breathing episodes were measured in successive 2-hour periods. Fig. 3 shows the pooled values for breathing incidence and episode duration before, during, and after clonidine infusion for each preparation. Each preparation was its own control and comparisons were made only between data from the same preparation under different conditions. Incidence and duration were significantly reduced during infusion and increased in the postinfusion period. In all experiments the incidence decreased; the median change was −66% (range, 10% to 75%; $p = 0.00004$). Ten percent of the 2-hour periods measured showed zero breathing incidence during clonidine infusion. Duration of breathing episodes also decreased during clonidine infusions by a median of −55% (range, 19% to 79%; $p < 0.0001$) compared with control.

In the 10-hour period after infusion, both incidence and duration of breathing episodes increased signifi-

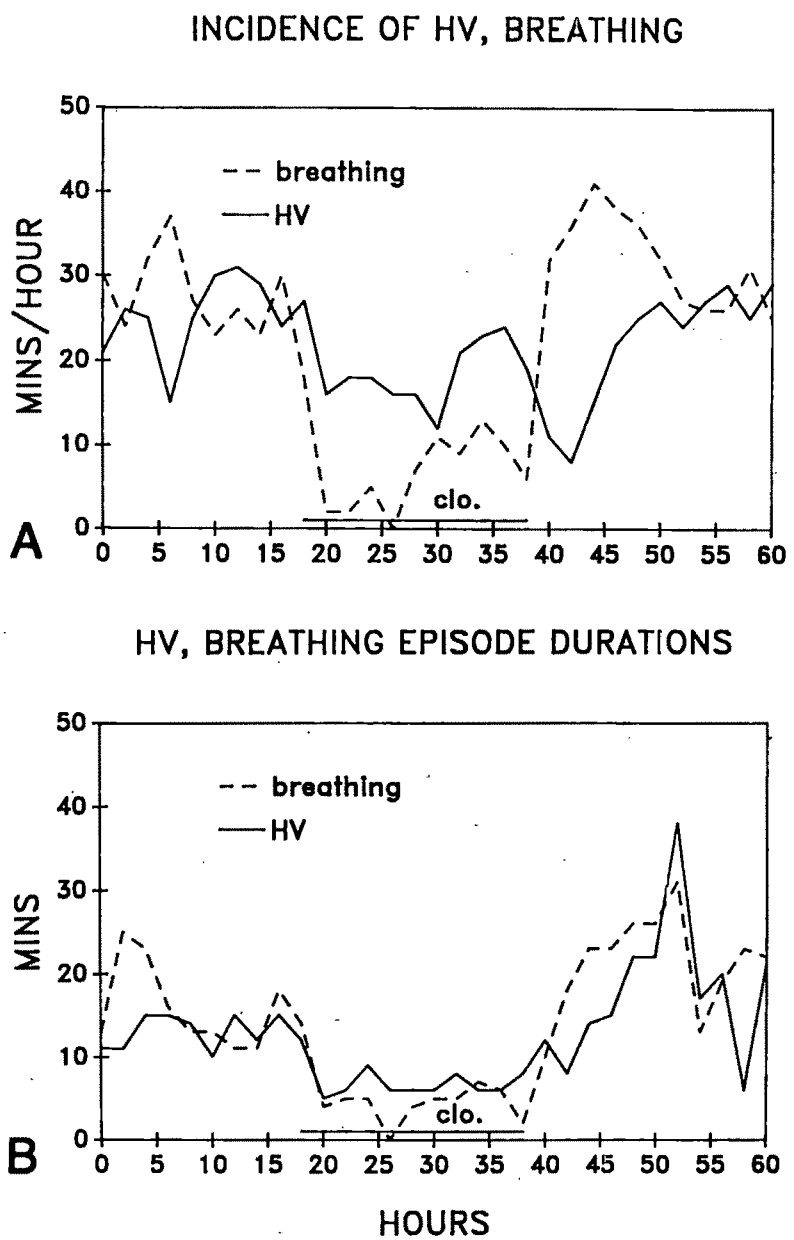

Fig. 2. Typical changes in **(A)** incidence and **(B)** episode duration for breathing and high-voltage electrocortical activity associated with a 20-hour infusion of clonidine via intraventricular catheter. Breathing incidence, episode duration, and high-voltage electrocortical activity duration were reduced during infusion and increased during recovery. High-voltage activity incidence in this case was relatively unaffected.

cantly above control. Breathing incidence increased by a median of 32% (range, 4% to 71%; $p = 0.01$) and 37% of observations showed breathing incidences of more than 40 minutes per hour in this period. Duration also increased significantly, and postinfusion breathing episodes lasting up to 4 hours occurred.

The amplitude of breathing in the postinfusion period appeared to be greater than control, and this was confirmed in one preparation in which the diaphragm electromyographic signal was processed by a quantitative (nonleaky) integrator, showing a transient twofold to threefold increase over control during the postinfusion period. The delay between the end of infusion and the onset of continuous breathing varied between less than 1 hour and more than 10 hours. During the postinfusion hyperpnea, breathing was not always confined to low-voltage electrocortical activity. Fig. 4 shows an example where breathing continued through high-

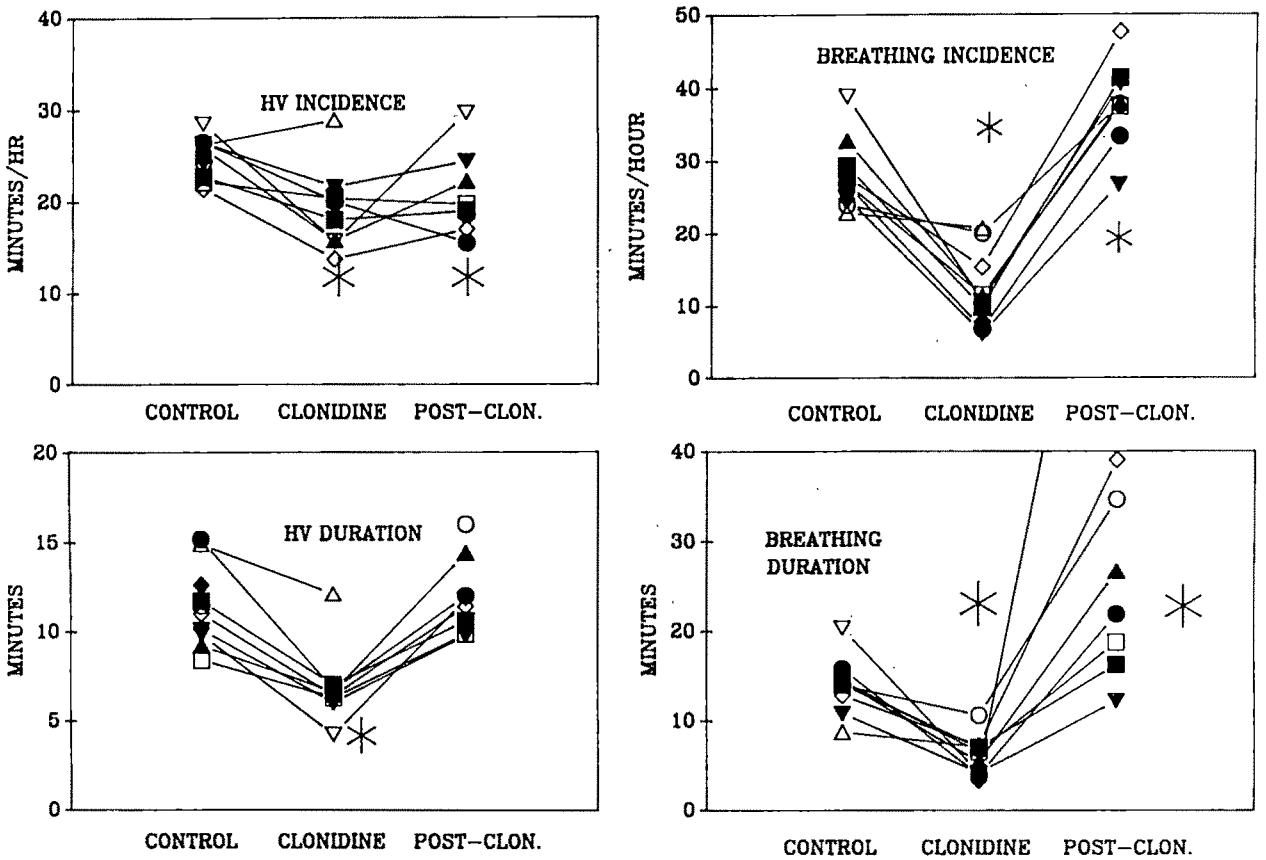

Fig. 3. Pooled values for high-voltage activity and breathing incidence and episode duration for each preparation before, during, and after clonidine infusion. The *lines* join points calculated from all data from a single preparation. Significant differences between control and experimental pooled data are indicated by *asterisks* (comparison of paired data by ranked-pairs test).

voltage electrocortical activity, during which there was nuchal activity and an increase in amplitude of breathing. This association of breathing, electrocortical, and nuchal activity is abnormal, occurring rarely if at all under control conditions.

Electrocortical activity. The incidence and episode durations of high-voltage electrocortical activity were measured over successive 2-hour periods. Fig. 3 shows the pooled values for incidence and episode duration before, during, and after clonidine infusion for each preparation. Significant differences from control ($p < 0.05$ by ranked-pairs test) are shown by asterisks. Each preparation was its own control and comparisons were made only within preparations. Clonidine significantly reduced both the incidence and duration of high-voltage electrocortical activity. The incidence of high-voltage activity decreased in all but one preparation; the median change was −26% (range, +10% to −46%, $p < 0.005$). After clonidine infusion the incidence of high-voltage electrocortical activity increased, but over the 10-hour postinfusion period values were still significantly below control (median change of −11%, range +4% to −41%; $p = 0.04$).

High-voltage electrocortical activity episode duration decreased in all preparations during infusion by a median of −40% (range, −19% to −57%; $p = 0.003$). After infusion the duration increased again to equal the control value.

In three preparations relative estimates were made of the mean amplitude of the high-voltage electrocortical activity signal in control, infusion, and postinfusion conditions. Tracings were made from the original recordings of electrocortical activity signals that had been rectified and processed by a leaky integrator (time constant, 1 second). Episodes of high-voltage electrocortical activity were readily identifiable as sections of integrated electrocorticogram tracings elevated above the low-voltage baseline. The raw electrocorticogram signal was also displayed and allowed confirmation of high-voltage episodes. The duration of each such episode was measured and the tracing cut out and weighed to find its area (signal power integrated over

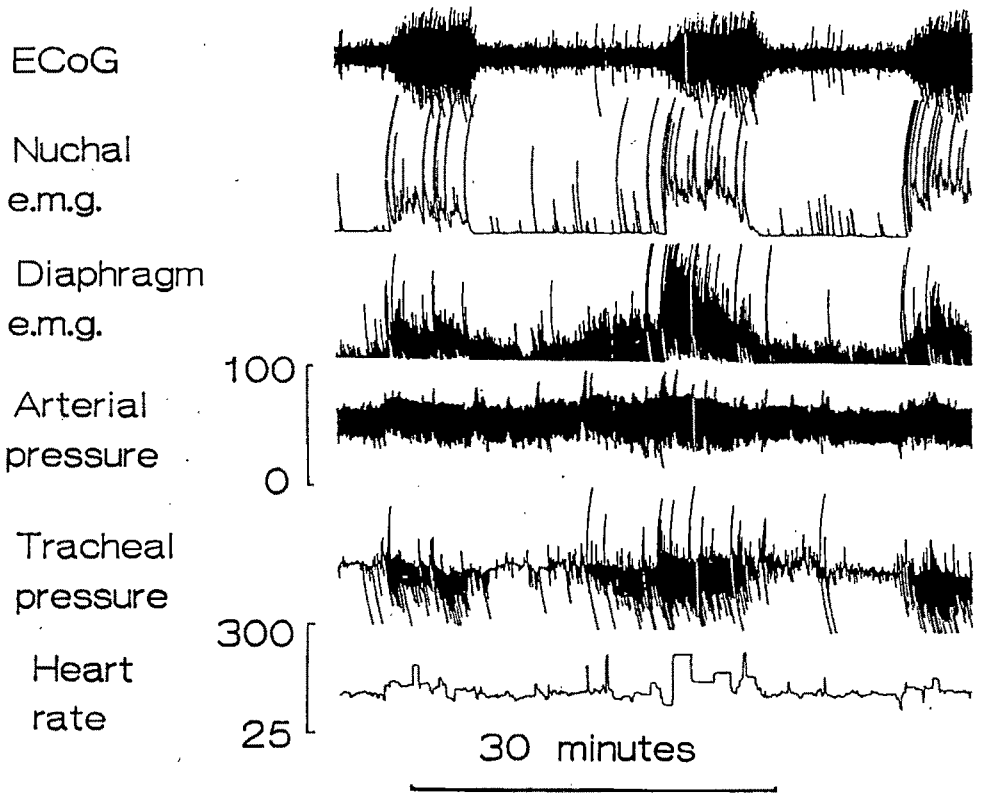

Fig. 4. Breathing, nuchal, and diaphragm electromyographic activity in a fetal lamb during recovery from clonidine infusion via intraventricular catheter. During this period hyperpnea frequently occurred, with breathing continuing in both low-voltage and high-voltage electrocortical activity as in this example.

time). The mean height was then calculated to provide a measure of the mean signal power during the episode. There were no consistent differences between control, infusion, and postinfusion values for mean heights in these preparations.

Nuchal activity. The nature of the chart recordings and of the pattern of nuchal muscle activity did not lend themselves to quantitative analysis by the methods available and no measurements were made. It was apparent that there was less nuchal activity during clonidine infusion: peaks of integrated electromyographic activity were lower and less frequent than in control conditions, although some activity was still present. Although nuchal activity remained episodic, the relation between episodes of breathing and high-voltage electrocortical activity was abnormal. During control periods nuchal activity was almost entirely confined to high-voltage as usual, but during clonidine infusions the small amount of nuchal and diaphragm activity tended to occur together during low-voltage electrocortical activity (Fig. 1). Nuchal activity increased again in the postinfusion period but had no consistent relationship to breathing.

Heart rate and blood pressure. There was no significant difference between high-voltage and low-voltage electrocortical activity in either rate or pressure. Mean control heart rate was 141.7 ± 3.3 per minute in high-voltage electrocortical activity and 137.5 ± 3.7 in low-voltage electrocortical activity (not significant by paired t test). Mean control arterial pressures were 48.8 ± .09 mm Hg (high-voltage electrocortical activity) and 52.1 ± 1.1 mm Hg (low-voltage electrocortical activity) (not significant by paired t test; all values are stated as means ± SEM). Each value is derived from 134 observations on six fetal lambs. Because low-voltage and high-voltage control data were not significantly different, values were pooled for comparison with clonidine responses. Contrary to expectation, clonidine did not lower fetal arterial pressure. The mean systolic pressure was 55.9 ± 5.1 mm Hg (control) and 56.8 ± 5.1 mm Hg (infusion) (difference not significant). However, heart rate was significantly reduced by clonidine infusion. Control mean was 158.8 ± 20.5 beats/min and during infusion the rate was 134.5 ± 18.4 beats/min ($p < 0.02$ by paired t test). Each mean is derived from a total of 134 observations.

Comment

This study confirms and extends an earlier report[5] that clonidine effectively inhibits fetal breathing by a direct action on the brain stem. In this study postinfusion hyperpnea also occurred, and both the incidence and episode duration of high-voltage electrocortical activity were reduced during and after central infusion. Infusion of clonidine was associated with inhibition of nuchal muscle activity and a fall in heart rate but fetal arterial pressure and blood gases remained unchanged.

The small cerebrospinal fluid volume and long catheters made sampling of cerebrospinal fluid impractical; thus the clonidine concentration in the cerebrospinal fluid is not known. The dose rate was 9 μg/hr or approximately 3 μg/kg/hr to the fetus (0.15 μg/kg/hr to the fetomaternal unit). The women in the study by Horvath et al.[1] received up to 1800 μg per day in two doses or approximately 12 μg/kg in each dose. If a steady state is assumed, this dose was equivalent to about 1 μg/kg/hr, but the postmedication peaks would have been higher. Thus the fetal dose rates used in this study were probably close to the maximum dose used in the clinical trials reported by Horvath et al. The infusion route directly into the ventricles probably did not affect the results because in most respects the data are qualitatively similar to those obtained in the previous study with systemic injections.[5] Clonidine did not cause apnea postnatally under physiologic conditions,[6] and a related agent, xylazine, induced tachypnea in adult sheep.[9] Clonidine had no effect on minute ventilation or breathing pattern in adult cats.[10] However, clonidine reduced phrenic discharge in paralyzed, anesthetized, and ventilated cats,[11] and clonidine and noradrenaline both inhibited rhythmic respiratory neural activity in the isolated brain stem of the newborn rat.[12] The inhibition was blocked by phenoxybenzamine, a nonspecific α-adrenergic antagonist. Under these conditions the respiratory nuclei were isolated from peripheral feedback regulation as in the fetus, and this may be a necessary condition for clonidine to cause apnea. Clonidine stimulates α_2-adrenergic receptors and reduces the rate of noradrenaline turnover in the brain.[13] We suggest that tonic activity in an α_1- or β-noradrenergic pathway is necessary to maintain fetal breathing and that fetal apnea can be caused by blocking this activity. The locus coeruleus with its high concentration of α_2 receptors[14] and adrenergic outflow to much of the brain stem is a possible site of such an action.

The mechanism of the postinfusion hyperpnea is unknown. A possibly analogous rise in respiratory rate, locomotor activity, and the incidence of body shakes in rats 8 to 12 hours follows a 10-day infusion of clonidine.[15] Both effects may result from prolonged inhibition of noradrenergic neurones, perhaps leading to an accumulation of transmitter or to hypersensitivity of postsynaptic neurones to norepinephrine. Chronic clonidine treatment has been shown to desensitize postsynaptic α_2 receptors,[16] and this represents another possible mechanism for the postinfusion hyperpnea. The increased breathing incidence in the fetus during this time was associated with an increased incidence of low-voltage electrocortical activity, although this alone could not account for the hyperpnea: breathing occasionally also occurred during high-voltage electrocortical activity in the postinfusion period. Blood gas levels were not significantly different from control during this period.

Clonidine altered the normal regular cycling of fetal electrocortical activity states, both during and after the infusion. Episodes of high-voltage electrocortical activity became shorter and the incidence of high-voltage activity was reduced during infusion, followed by recovery within 8 to 10 hours of the end of infusion. These effects differ from those reported after systemic injections, which caused an immediate but transient shift to high-voltage activity. The difference may be a result of the different time course of central clonidine levels. Systemic bolus injections produce a rapid rise and fall, whereas central infusion causes a slow rise to a steady concentration. However, in both studies the previously regular electrocortical activity cycling became rapid and irregular for some hours after administration of clonidine. Effects of clonidine on sleep state have been described in other species: it reduces the incidence of rapid eye movement sleep in rat pups,[17] and induces cortical synchronization (high-voltage electrocortical activity) in rabbits.[18] Clonidine inhibits the release of 5-hydroxytryptamine (serotonin) from raphe neurones indirectly[2] and could affect sleep-state regulation by this means. Because fetal activity is affected by sleep state, it is possible that changes in sleep-state cycling could affect motor development.

In conclusion, we have demonstrated a prolonged inhibition of fetal breathing during central clonidine infusion with prolonged postinfusion hyperpnea. Changes in electrocortical cycling also occurred. These findings support the hypothesis of a central noradrenergic drive important in maintaining fetal but not neonatal breathing, and this may be an important insight into perinatal changes in the respiratory control system. Such changes are as yet poorly understood[19] but it seems likely that failure to coordinate them could lead to respiratory instability and a tendency to apnea in the newborn. The depression of fetal breathing by clonidine may also have direct clinical significance. It has been shown repeatedly that any interference with breathing in fetal lambs results in lung hypoplasia[20] and

this is probably also true for humans.[21] Until further information is available, clonidine should be used with caution during pregnancy.

We thank Victor Chen for surgical assistance and William Ellis for help with data analysis.

Dose response of thyrotropin-releasing hormone on pulmonary maturation in corticosteroid-treated preterm rabbits

Bannie L. Tabor, MD,[a] Machiko Ikegami, MD, PhD,[b] Alan H. Jobe, MD, PhD,[b] Takako Yamada, MD,[b] and Sidarto Bambang Oetomo, MD, PhD[b]

Torrance, California

The dose-response effect of thyrotropin-releasing hormone in enhancing pulmonary maturation was investigated with six dosing regimens. Pregnant does received thyrotropin-releasing hormone (5, 10, or 50 μg/kg every 12 hours for four doses or one dose of 20 μg/kg) in conjunction with betamethasone beginning on day 25 of gestation, with betamethasone alone or saline solution used as comparison treatment groups. Half of the newborn rabbits received supplemental surfactant therapy after delivery on day 27, and all were ventilated on a ventilator plethysmography system for 30 minutes. There were no differences among the four thyrotropin-releasing hormone doses in surfactant pool sizes, compliances, or proteins leak into or out of the air spaces. The groups that received multiple doses of thyrotropin-releasing hormone had significantly higher perinatal loss rates than the single-dose group. The lungs of the group treated with thyrotropin-releasing hormone plus steroid and the rabbits treated only with steroid were more compliant than the controls without surfactant therapy, and showed significant improvements in protein leak. The addition of thyrotropin-releasing hormone to betamethasone improved several of the protein leak measurements compared with use of betamethasone alone. These results question the necessity of multiple doses of thyrotropin-releasing hormone to induce pulmonary maturation, especially when the higher perinatal mortality and the theoretical long-term effects of fetal hyperthyroidism on thyroid axis function are considered. (Am J Obstet Gynecol 1990;163:669-76.)

Key words: Thyrotropin-releasing hormone, corticosteroids, pulmonary maturation

The concept of hormonal induction of pulmonary maturation has been experimentally demonstrated and clinically applied with the use of antenatal corticosteroids for the prevention of respiratory distress syndrome in the preterm neonate.[1] However, many preterm deliveries occur too quickly to benefit from maternal corticosteroid treatments, or the use of corticosteroids is relatively contraindicated. In addition, only about 50% of preterm infants appropriately treated benefit from maternal corticosteroid therapy.[1] Several other agents have been evaluated for properties similar or additive to those of corticosteroids.[2] Thyroid hormones, alone and in conjunction with steroids, have been shown to improve many of the in vitro measurements used to assess pulmonary maturation.[1,2] Because these hormones do not cross the placenta in appreciable amounts, thyrotropin-releasing hormone, a tripeptide that readily crosses the placenta, has been investigated as a means to stimulate the fetal thyroid axis and hence increase circulating levels of thyroid hormones in the fetus. Previous rabbit and early clinical studies have used doses of 15 to 40 μg of thyrotropin-releasing hormone per kilogram of maternal body weight per day for 48 to 72 hours before delivery.[3-5] Multiple divided doses have been used to theoretically maintain elevated fetal triiodothyronine and thyroxine levels during the course of therapy. These studies have suggested improvements in pulmonary maturation with the combination of thyrotropin-releasing hormone and corticosteroids that are superior to either hormone individually. The purpose of this study was to investigate possible dose-response effects of thyrotropin-releasing hormone on induction of pulmonary maturation when used in conjunction with betamethasone, either alone or with supplemental surfactant therapy.

Thyrotropin-releasing hormone purchased from Bachem (Torrance, Calif.). Betamethasone as Celestone Soluspan was a gift from Schering Corp. (Kenilworth, N.J.).

hormone we used were selected to bracket the doses used previously. In addition, we administered 20 μg/kg in a single injection to evaluate the efficacy of a single dose regimen. Rabbits in all four thyrotropin-releasing hormone dose groups also received betamethasone to evaluate a dose response to thyrotropin-releasing hormone in hormonal combination treatment. The dose of betamethasone used (50 μg/kg) was previously shown to achieve the same beneficial effects as higher doses in this model while minimizing perinatal mortality.[7] Two control groups were used to evaluate possible differences between the single and multiple intravenous injections. The guidelines for the care and use of animals approved by our institution were followed during the experiment.

Preparation of rabbits. On day 27 of gestation the pregnant does were lightly anesthetized with intravenous diazepam, given supplemental oxygen via face mask, and delivered via cesarean section with use of spinal anesthesia. The newborn rabbits were weighed and given 10 mg/kg ketamine and 0.1 mg/kg acepromazine by intraperitoneal injection. The trachea of each rabbit was isolated and a tracheal tube made from a 18-gauge needle was tied into the trachea. The chest was compressed and released as 0.2 ml of 0.45% sodium chloride containing either 1 μCi iodine 125–labeled albumin or natural sheep surfactant (50 mg total lipid per kilogram of body weight) with 1 μCi ^{125}I were injected intratracheally to alternate fetuses from each litter.[3]

After the intratracheal injection approximately five breaths of 100% oxygen were given with an anesthesia bag and manometer to initiate ventilation. The rabbits were then transferred to a ventilator plethysmography system temperature controlled at 37° C.[3] Initial ventilation was with 100% oxygen at a rate of 40 breaths/min, an inspiratory time of 0.7 seconds, a peak inspiratory pressure of 35 cm H_2O, and an end expiratory pressure of 0. The tidal volume was measured frequently with a pneumotachometer and maintained at 10 to 12 ml/kg by adjusting the individual peak inspiratory pressures.[3]

Each rabbit received 0.2 ml of saline solution containing 1 μCi ^{131}I-albumin via the external jugular vein immediately after placement on the ventilator. The rabbits were ventilated for 30 minutes and then killed with intrathecal injections of lidocaine. The chest was opened and a heparinized blood sample was drawn from the heart. An aliquot of this sample was used to measure P_{CO_2}. A second aliquot was used for measurements of labeled albumin and hemoglobin concentration. The sex of each rabbit was determined by examination of the internal gonads.[8]

Processing of samples. The lungs of the newborn rabbits were thoroughly lavaged with five aliquots (1 to 1.5 ml each) of 0.9% sodium chloride.[3] The pooled volume was recorded as the alveolar wash. The lungs were removed and weighed. The alveolar wash, lungs, and blood aliquots and triplicate samples of the ^{131}I and ^{125}I used for the initial injections were counted for radioactivity. The lungs were then homogenized in 4 ml of 0.9% saline solution and the volume recorded. The contribution of intravascular blood to the radioactivity associated with the lung was calculated by measuring the hemoglobin content and radioactivity of the blood and the lung, and was subtracted from the total radioactivity of the lung.[3]

Lipid extracts of aliquots of the alveolar wash and the lung homogenate were prepared with chloroform/methanol (2:1, vol/vol).[9] The extracts were treated with osmium tetroxide; saturated phosphatidylcholine was isolated by alumina column chro-

matography and quantified by phosphorus assay.[10, 11] The protein content of each alveolar wash was quantified.[12]

Materials. Radiolabeled albumin was prepared by iodination with carrier-free ^{131}I or ^{125}I (New England Nuclear, Boston) using chloramine-T and monomer standard bovine serum albumin (Miles Laboratories, Elkhart, Ind.). The iodinated albumin was extensively dialyzed, and the incorporation was verified by trichloroaceteic acid precipitation. The surfactant was isolated by a series of differential and sucrose density-gradient centrifugation steps from alveolar washes from adult sheep.[13]

Data analysis. Animals were excluded from the final analysis if upper airway leaks occurred during placement of the trachea tube, a pneumothorax occurred during ventilation, or the final P_{CO_2} was greater than 70 mm Hg. The ^{125}I and ^{131}I-albumin radioactivity of the alveolar wash and the lung tissue were expressed as the percent recovery of the respective quantities injected. A compliance value was calculated for each rabbit at 5, 10, 20, and 30 minutes after the initiation of ventilation by dividing the measured tidal volume by the peak inspiratory pressure and the body weight in kilograms. All values are reported as means ± SEM. Statistical analysis was performed using a one-way analysis of variance followed by the Student–Newman-Keuls correction for multiple comparisons. Initially an analysis was performed among the four thyrotropin-releasing hormone dose groups to identify any dose effects. If no differences were found among the thyrotropin-releasing hormone groups, they were combined into a single thyrotropin-releasing hormone group and compared with the steroid and control groups. The two control groups were not different and were combined for the analysis. Mortality rates were examined with χ^2 analysis with the appropriate degrees of freedom. Unpaired t tests were used to determine any sex-dependent differences within groups. No sex differences in any parameters were noted; sexes within groups were combined for subsequent analysis. Significance was accepted at levels of $p < 0.05$.

Results

Condition of animals. There were no perinatal losses (abortions or stillbirths) in the control group, and only one in the steroid alone group (Table II). In contrast, groups treated with the multiple doses of thyrotropin-releasing hormone had significantly higher perinatal mortality than the steroid-only or control groups ($p < 0.01$). The single 20 μg/kg dose group's loss rate was not significantly different from the steroid alone, the control, or the 10 μg/kg dose group but was less than the 5 and the 50 μg/kg dose groups ($p < 0.001$). There were no differences in the mortality rates between the multiple dose thyrotropin-releasing hormone groups. One of the 5 μg/kg litters, containing 10 fetuses, and two of the 50 μg/kg litters, totaling 16 fetuses, were delivered prematurely after the last dose of thyrotropin-releasing hormone. In terms of body weight there was no difference between the thyrotropin-releasing hormone groups, or between groups with or without surfactant treatment. The 5, 50, and combined thyrotropin-releasing hormone groups had significantly lower mean birth weights than the steroid and control groups when the surfactant treatment subgroups were combined ($p < 0.05$).

Ventilatory status. The ventilator strategy used was successful in maintaining mean tidal volumes in the desired range for all treatment groups (Table III). Among the individual thyrotropin-releasing hormone groups, the only significant difference in any of the ventilatory parameters was that the 10 μg/kg thyrotropin-releasing hormone group treated with surfactant required a higher mean peak inspiratory pressures than the respective 5 and 20 μg/kg groups ($p < 0.05$). No clear thyrotropin-releasing hormone dose effects or tendencies were seen within the respective surfactant treatment groups in terms of compliance. In the absence of exogenous surfactant, the control group required a higher mean peak inspiratory pressures than the combined thyrotropin-releasing hormone group ($p < 0.05$), and was less compliant than the combined thyrotropin-releasing hormone group and the group treated with steroid alone at 30 minutes ($p < 0.05$). These differences in compliance and peak inspiratory pressures disappeared when the rabbits were treated with surfactant. The rabbits that received thyrotropin-releasing hormone showed a 18% greater improvement in compliance at 30 minutes with surfactant therapy than the group treated with steroid only, although there were no significant differences in the final values.

Surfactant pool size. The amount of saturated phosphatidylcholine in the alveolar wash and the total lung (lung homogenate plus alveolar wash) were measured to assess the effects of thyrotropin-releasing hormone on surfactant pool size in the absence of supplemental surfactant (Fig. 1). The 50 and the single 20 μg/kg doses resulted in a twofold increase in alveolar wash saturated phosphatidylcholine over the 5 and 10 μg/kg doses, but these findings were not significant. Similarly, there were no differences among the four thyrotropin-releasing hormone doses in terms of total lung saturated phosphatidylcholine. Thyrotropin-releasing hormone combined with betamethasone treatment did not significantly increase surfactant pool size when compared with the control group. Although the nonsurfactant-treated combined thyrotropin-releasing hormone plus beta-

methasone group had alveolar wash and total lung pool sizes that were respectively 60% and 15% greater than the litters treated only with steroid, these differences were not statistically significant. In the surfactant-treated groups no differences were found between any of the thyrotropin-releasing hormone groups or between the combined thyrotropin-releasing hormone group, the steroid-only group, and the control in either alveolar wash or total lung saturated phosphatidylcholine.

Protein leak. The percent recovery of intravascular ^{131}I-albumin in the alveolar wash and total lung was used as a measurement of the accumulation of intravascular protein in the alveolus and lung tissue; a higher percent recovery indicated greater protein leak into the lung (Fig. 2). The alveolar wash recovery was similar for the four groups. Although surfactant treatment decreased the recovery of ^{131}I-albumin by more than fourfold, there were no thyrotropin-releasing hormone dose-dependent effects. The total lung recoveries similarly failed to show significant differences or a dose-related trend. The alveolar wash recovery in the combined thyrotropin-releasing hormone group was almost half that of the control in both the presence ($p < 0.05$) and absence of surfactant treatment ($p < 0.01$), and the total lung recovery was significantly decreased in the absence of surfactant treatment ($p < 0.05$). Treatment with betamethasone alone decreased the percent recovery of labeled albumin in relation to the controls in the alveolar wash ($p < 0.01$) and the total lung ($p < 0.05$) in the absence of surfactant therapy. In examining the effects of thyrotropin-releasing hor-

mone and corticosteroids, thyrotropin-releasing hormone plus betamethasone therapy in the combined thyrotropin-releasing hormone group significantly decreased the percent recovery of labeled albumin in relation to betamethasone alone for all measurements except the alveolar wash recovery in the nonsurfactant-treated group ($p < 0.05$).

The total amount of protein recovered in the alveolar wash showed similar responses to thyrotropin-releasing hormone therapy independent of dose. The addition of surfactant therapy decreased the alveolar wash total protein from 115.7 ± 8.4 to 95.6 ± 5.6 mg/kg in the combined thyrotropin-releasing hormone group, and from 127.0 ± 8.4 to 116.7 ± 21.9 mg/kg in the group treated with steroid only. Although the thyrotropin-releasing hormone groups exhibited a 100% to 200% greater decrease with surfactant treatment than the group treated with steroid only, there were no significant differences in the amount of protein recovered from the air spaces when compared with the steroid groups. The alveolar wash protein in the control group was 242.4 ± 18.8 mg/kg, 70% to 130% higher than the hormonally treated rabbits without surfactant treatment ($p < 0.01$). Although the recovery in the control group significantly decreased to 159.7 ± 16.5 mg/kg with surfactant therapy, it remained 40% to 60% higher than in the hormonal treatment groups ($p < 0.05$).

The percent recovery of the intratracheal instilled ^{125}I reflects the movement of protein from the air spaces; a lower percent recovery indicates more movement or leak from the lung. No differences or trends occurred with the different thyrotropin-releasing hormone doses in either the alveolar wash or total lung recovery (Table IV). Without surfactant therapy the recovery in the alveolar wash in the individual and combined thyrotropin-releasing hormone groups and the group treated with steroid only was 25% to 35% less than the controls ($p < 0.05$). There were no differences between the thyrotropin-releasing hormone and steroid-only groups in alveolar wash recovery, or among any groups in total lung recovery. Surfactant therapy resulted in a higher percent recovery in (i.e., decreased protein leak from) the air spaces and lung. No differences were noted between the controls and the hormonal treatment groups.

Comment

The initial interest in the effects of thyrotropin-releasing hormone on enhancing pulmonary maturation arose from its potential as a means for transplacental stimulation of the fetal thyroid axis. Thyrotropin-releasing hormone does cross the placenta in the rat, rabbit, primate, and in humans.[14-16] Azukizawa et al.[14] demonstrated that maternal administration of 10 μg/kg of thyrotropin-releasing hormone in the rhesus monkey resulted in a fivefold increase in fetal TSH at 1 hour and a twofold to threefold increase in triiodothyronine and thyroxine at 2 hours. In humans Moya et al.[15] noted a fourfold increase in cord blood TSH and a twofold increase in cord triiodothyronine with 400 or 600 μg of thyrotropin-releasing hormone given 2 hours before delivery.

With the historical experience of corticosteroids requiring 48 hours before beneficial effects are noted, and the theory that the mechanism of action of steroids and thyrotropin-releasing hormone involve, at least in part, the receptor-mediated induction of specific enzyme systems, the studies that have examined the effects of thyrotropin-releasing hormone in conjunction with corticosteroids have used >24-hour dosing regimens.[3-6] The doses of thyrotropin-releasing hormone chosen have been based on the results of the studies outlined above. Most of the studies have used multiple doses of thyrotropin-releasing hormone in an attempt to obtain elevated levels of triiodothyronine and thyroxine in the fetus for much of the 24 to 72 hours

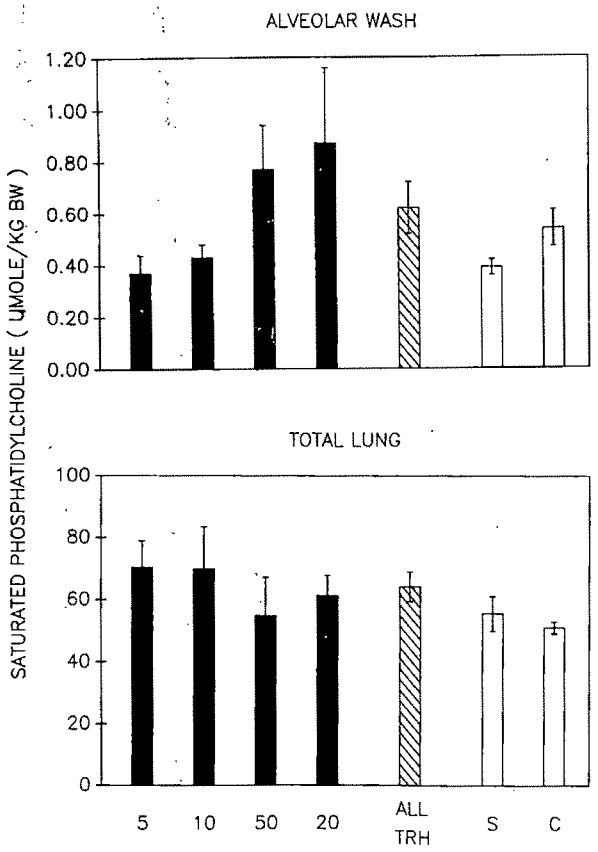

Fig. 1. Amount of saturated phosphatidylcholine in the alveolar wash and total lung (alveolar wash + lung homogenate) in the animals not treated with supplemental surfactant. There were no significant differences among the individual multiple (5, 10, 50 μg/kg) or single (20 μg/kg) thyrotropin-releasing hormone dose groups, or among the combined thyrotropin-releasing hormone *(ALL TRH)*, steroid only *(S)*, or control *(C)* groups.

of exposure. Ikegami et al.,[3] using 20 μg/kg of thyrotropin-releasing hormone every 12 hours for four doses in the 27-day preterm rabbit model, noted an improvement in compliance with thyrotropin-releasing hormone plus betamethasone relative to thyrotropin-releasing hormone or betamethasone alone when the rabbits were treated with surfactant. Suggestive improvements in these measurements and in protein leak measurements in the combination group without surfactant therapy were also noted. Oulton et al.[5] found increases in the intracellular, but not the extracellular, surfactant pool sizes in the 27-day gestation rabbit with intraperitoneal fetal cortisol injections followed by single daily doses of 40 μg/kg thyrotropin-releasing hormone beginning on day 24. No significant differences were noted among 1, 2, or 3 days of thyrotropin-releasing hormone therapy. Liggins et al.,[17] using direct fetal infusions of 25 μg thyrotropin-releasing hormone per hour over 6½ days, cortisol, or both, in the preterm lamb, found significant increases in alveolar wash–saturated phosphatidylcholine and lung distensibility and stability when compared with cortisol alone. In the one published clinical trial to date, Morales et al.[4] compared thyrotropin-releasing hormone (400 μg every 8 hours for six doses) and betamethasone (12 mg every 24 hours for two doses) with betamethasone alone. They found a significantly higher success rate (no respiratory distress syndrome if delivered within 1 week or a mature lecithin/sphingomyelin ratio if undelivered after 1 week) with thyrotropin-releasing hormone and betamethasone (61%) versus betamethasone alone (46%). In addition, the thyrotropin-releasing hormone plus steroid group required less assisted ventilation (2.1 versus 5.1 days) and had a lower incidence of bronchopulmonary dysplasia (8% versus 24%).

When our dosing regimens are compared with these studies, we have administered both higher and lower single and cumulative doses of thyrotropin-releasing hormone. The tendencies for the rabbits treated with thyrotropin-releasing hormone plus steroid to be more compliant and have larger surfactant pools than the group treated with steroid only are consistent with the findings of Ikegami et al.[3] and Oulton et al.[5] The thyrotropin-releasing hormone and steroid effects on ^{125}I-albumin recovery, suggesting increased leak from the air spaces, may represent increased surface area (increased alveolarization) or maturational effects on alveolar epithelial permeability, as noted previously with betamethasone.[7] The decreased recovery of ^{131}I from the alveolar wash and total lung indicates attenuated leak from the pulmonary vasculature into the lung and air spaces. This suggests a maturational effect of these hormones on the vascular endothelium. The combined effects of thyrotropin-releasing hormone and corticosteroids on the vascular endothelium and the alveolar epithelium are superior to corticosteroids alone. Because the proteins recovered in the alveolar wash presumably contribute to the formation of hyaline membranes and may interfere with the function of surfactant, these improvements induced by the combined hormonal treatment may play a role in the improvements Morales et al.[4] noted in terms of duration of assisted ventilation and incidence of bronchopulmonary dysplasia.[18]

This study demonstrated no differences among four different thyrotropin-releasing hormone dosing regimens. When the results are analyzed for trends that would suggest a dose response to thyrotropin-releasing hormone, no clear, consistent tendencies are found, regardless of either the individual dose size or the total amount. One alarming trend is noted. The litters treated with the multiple-dose regimens experienced a twofold to threefold increase in perinatal loss rate compared with the litters treated with a single-dose regimen. Significant mortality rates have been previously observed with thyroid hormones alone and with glucocorticoids in this model.[3, 19] Devaskar et al.[20] postulated that these hormones may deplete myocardial glycogen, which could result in fetal death. The

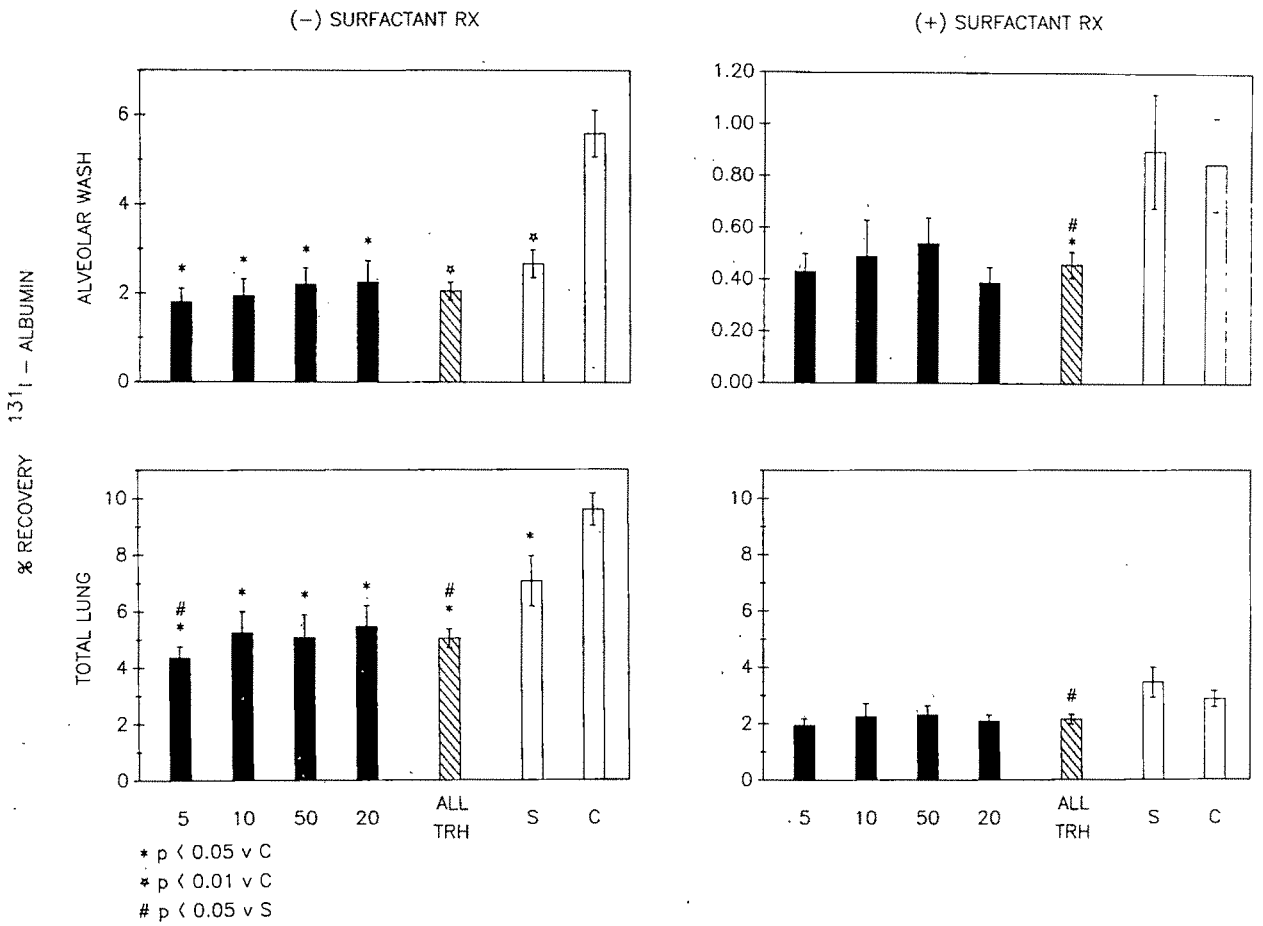

Fig. 2. Percent recovery of ^{131}I-albumin from the alveolar wash and total lung. There were no differences among the individual thyrotropin-releasing hormone dose groups, with or without surfactant therapy. The percent recovery from the alveolar wash and total lung for all the treatment groups was significantly less than the control in the absence of surfactant therapy. The total lung recovery in the combined thyrotropin-releasing hormone and the 5 μg/kg groups was also less than the steroid-only group. With surfactant treatment, only the combined thyrotropin-releasing hormone group was significantly less than the control group in alveolar wash recovery and the steroid-only group in both alveolar wash and total lung recovery.

higher loss rate observed with the multiple doses of thyrotropin-releasing hormone could result from more severe or complete myocardial glycogen depletion.

The lack of a dose response in our study raises questions with regard to the mechanism action of thyrotropin-releasing hormone in enhancing pulmonary maturity. The systems responsible for the observed effects of thyrotropin-releasing hormone may not respond to thyroid hormones in a dose-dependent manner, may do so at lower levels than those induced by the doses of thyrotropin-releasing hormone used here, or may be a result of other actions of thyrotropin-

releasing hormone, either directly as a neurotransmitter, or indirectly from stimulation of fetal breathing or release of other hormones, such as prolactin.[17,21] These maturational processes may be initiated once a threshold concentration of thyrotropin-releasing hormone, which possibly completely binds the appropriate receptors, is reached. The results obtained with the single 20 μg/kg dose suggest that these levels need only be maintained for a relatively brief period of time. This hypothesis questions the efficacy, and the necessity, of using multiple doses of thyrotropin-releasing hormone to stimulate a system that may be activated after the first dose.

In this light, two points must be considered that may be of more than theoretical interest. The first concerns the increased perinatal mortality observed with the multiple-dose regimens. Although use of thyrotropin-releasing hormone did not increase mortality in the clinical study, the question of increased risk with the multiple-dose regimen is raised. The second point to be considered concerns the concept of receptor plasticity and hormonal imprinting. The number and affinity of hormone receptors change during the perinatal period.[22] This adaptive process is sensitive to internal (genetic) and external (hormonal) influences. The final receptor numbers and binding capacity, and hence the adult behavior, of a particular system may be substantially affected by perinatal hormonal levels. Permanent alterations in the hypothalamopituitary-thyroid axis in rats can be induced by neonatal hyperthyroidism.[23] Whereas the in utero levels of thyroid hormone achieved by maternal administration of thyrotropin-releasing hormone are surpassed by the postnatal thyroid surge, the effect of transient fetal hyperthyroidism on adult function of the thyroid axis is unknown and may prove to be deleterious. If subsequent clinical trials confirm the utility of this combined hormonal therapy, investigation of the efficacy of a single dose of thyrotropin-releasing hormone should be undertaken to minimize the risks to which the fetus is exposed in obtaining these benefits.

Definition of primiparas

To the Editors: I write in reference to the letter (Gooden MD. Defining "primiparas" [Letter]. AM J OBSTET GYNECOL 1989;161:1417) and reply (Thomson M. Reply [Letter]. AM J OBSTET GYNECOL 1989;161:1417) that appeared in the November 1989 issue of the JOURNAL. I agree with Dr. Goodman that the term "primipara" should be used as it is defined obstetrically. I trust that Dr. Thomson would not refer to the patient in question as being para 1 but will call them "1 para" by using the term primipara. Those who are and hold themselves to be educated professionals are held to a higher standard than generic dictionary writers. I urge the editors of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY to avoid the misuse of the term "primipara" within the covers of the JOURNAL.

Twin-to-twin transfusion syndrome

To the Editors: Drs. Danskin and Neilson should be congratulated for reevaluating the diagnosis of the twin-to-twin transfusion syndrome (Danskin FH, Neilson JP. Twin-to-twin transfusion syndrome: What are appropriate diagnostic criteria? AM J OBSTET GYNECOL 1989; 161:365-9). Their study focused on the posthoc situation after the delivery of a growth discordant pair (>20%) with or without hemoglobin difference of ≥5 gm/dl. They concluded correctly that neither permits a definitive diagnosis of the syndrome.

Twin-to-twin transfusion syndrome is a rare cause of intertwin growth disparity,[1] which mainly results from environmental rather than genetic factors. The findings of Danskin and Neilson are therefore unsurprising.

The twin-to-twin transfusion syndrome is an important and dangerous complication that must not be left for postpartum diagnosis. Bebbington and Wittman[2] listed the ultrasonographic criteria including (1) intertwin growth discordancy, (2) amniotic sacs of divergent size, (3) signs of hydrops in either twin or congestive heart failure in the recipient, (4) same sex of twins, (5) single placenta, and (6) separate cords differing in size and number of vessels. In addition, percutaneous umbilical cord sampling may disclose highly divergent hemoglobin levels. Finally, Doppler velocimetry has been claimed to diagnose twin-to-twin transfusion.[3]

In our experience, intensive and possibly invasive evaluations may be indicated in highly discordant twins as revealed by ultrasonography.[4] When combined with other features that indicate the twin-to-twin transfusion syndrome, rescue of one or both twins may be possible.

Isaac Blickstein, MD

Department of Obstetrics and Gynecology, Kaplan Hospital, Rehovot, Israel 76100

Reply

To the Editors: I appreciate the interest of Dr. Blickstein in our article. I am well aware of the ultrasonographic features of florid twin-to-twin transfusion syndrome. They are not subtle and they were described in our article. However, the question that we have been addressing (and to which this article contributes) is whether the presence of vascular anastomoses in monochorionic placentas contributes to a spectrum of adverse outcome (i.e., less unmistakable manifestations of twin-to-twin transfusion syndrome). Such studies require that appropriate criteria are established for diagnosis of the condition after birth. Dr. Blickstein may not be surprised that the finding of a hemoglobin difference >5 gm/dl plus a birth weight difference >20% is not definitive proof of twin-to-twin transfusion syndrome, but I suspect others will be surprised. Varying reports of the pattern of Doppler umbilical artery flow velocity waveforms in apparent twin-to-twin transfusion syndrome undoubtedly reflect a lack of satisfactory diagnostic criteria—thus concordant waveforms,[1,2] discordant waveforms,[3] cyclically discordant waveforms,[4] and no consistent pattern[5] have all been reported. Clearly, it is vital that the type of placentation be reported in any publication on the subject of twin-to-twin transfusion syndrome, but this is frequently not the case. We have found that vascular anastomoses in monochorionic placentas do not, in the absence of rare florid twin-to-twin transfusion syndrome, exert a strong influence on fetal growth or umbilical artery flow velocity waveforms.[6]

The management of twin pregnancy is perhaps the example par excellence in obstetrics of uncontrolled

observation passing as scientific fact leading to inappropriate intervention. The long-cherished concept that routine bed rest, for example, prolongs twin pregnancy can only now be confidently laid to rest.[7-9] If Dr. Blickstein has controlled data to indicate that invasive procedures improve fetal outcome in twin-to-twin transfusion syndrome he should be less coy in sharing such important observations with the medical community.

The importance of considering clinical usefulness in the evaluation of medical laboratory tests

To the Editors: The rapid proliferation of medical laboratory tests is providing the practicing physician with the choice of a wide variety of determinations, methods, and manufacturers. In the field of infectious diseases for example, because of the recognition of new infectious agents and the development of monoclonal and molecular techniques there is a remarkable increase in the number and types of laboratory tests and there is a wide variety of packaged test kits prepared by many different manufacturers. These tests are being marketed to both laboratories and physicians. The clinician is increasingly required to select (or have selected for him) not only a particular determination but also a specific method and manufacturer.

In the past, most laboratory methods were evaluated and chosen on the basis of the sensitivity and specificity of the method compared with a reference method. In some cases, further evaluation included the determination of the positive and negative predictive values of the test as applied to particular populations. Tests with "high marks" with these evaluations were then selected if their availability and cost were satisfactory.[1] It is apparent however, that even the best tests selected with these criteria may have little or no clinical usefulness.

Just two examples from the field of perinatal infectious diseases demonstrate the importance of clinical usefulness.

Example 1—Prediction of recurrent genital herpesvirus near the time of delivery—use of cesarean section:

For the past 15 to 20 years sensitive and specific tissue culture tests were used serially during pregnancy to identify asymptomatic genital herpes infections in high-risk women. If the tests were positive near term, the child was delivered by cesarean section. It was not until 1987 that a study was conducted to determine whether these serial prospectively conducted tests actually identified women who had herpes infections at the time of delivery.[2] The investigations showed no correlation between the serial test results and the presence of herpes infection at delivery. These tests are no longer recommended.[3,4]

Example 2—Use of immunoglobulin M (IgM) antibody to *Toxoplasma gondii* to diagnose acute infections during pregnancy:

With the availability of specific IgM tests for antibody to *Toxoplasma gondii* these tests have been used to identify pregnant women who may have had primary infection with this organism during pregnancy. If a woman had serologic evidence of primary toxoplasmosis, she was counseled on the possible serious effects on the developing fetus and the importance of starting chemotherapy or possibly a therapeutic abortion. In a more recent study, however, we showed that high titers of this antibody may persist for many years in some persons.[5] Thus we now know that the presence of high IgM titers cannot accurately distinguish a very recent or current infection from one that may have occurred several years earlier.

These two examples show the importance of considering clinical usefulness in the selection of tests to be used in the care of patients. In both instances large numbers of patients were tested at considerable cost in the belief that the tests had clinical value. In addition, major clinical decisions were made on the basis of the test results. Whereas the determinations provided relatively sensitive and specific information about the presence or absence of genital herpesvirus or IgM antibody to *Toxoplasma,* many years passed before the value of this information was considered in relation to the clinicaal problem. For herpes, after about 20 years of testing a study was finally conducted and it showed that the serial tests taken earlier in pregnancy did not predict the presence or absence of genital herpes at delivery. Thus on a scale of 0 to 100, the clinical usefulness of the test used for this purpose was very low.

Similarly for *Toxoplasma,* the tests themselves could be made quite accurate for the detection of IgM antibody; however, when we studied the persistence of this antibody we found that a number of patients retained very high antibody levels for many years. Therefore the presence of high titers of IgM antibody could not be used to accurately document the occurrence of an acute infection during pregnancy. Again, for this purpose the test had a very low clinical usefulness.

These are just two examples of medical laboratory tests with low clinical usefulness for the clinical applications described. The same tests have higher clinical usefulness when applied to other clinical problems. Many other examples could be described.

Numeric estimates of clinical usefulness can be determined by use of the same statistical methods used for sensitivity, specificity, and predictive values. However, the analysis must relate the laboratory data to the clinical information that is of greatest importance. For perinatal herpes, the most significant clinical usefulness would be the relation between the maternal preterm herpes cultures and herpes infection of the newborn child. This clinical usefulness has never been determined. The next most useful clinical usefulness is the relation between preterm cultures and genital herpes at delivery. This was finally determined in 1986 and led to the discontinuation of these procedures.

Clearly we must consider the clinical usefulness of each test in relation to the purpose for which it is being used. We must examine the clinical usefulness of the many tests that are already in use and we must require the inclusion of studies and analysis of clinical usefulness for new tests as they become available for clinical medicine.

Surrogate parenting contracts

To the Editors: La Puma et al.'s "Clinician Opinion" article about surrogacy (La Puma J, Schiedermayer DL, Grover J. Surrogacy and Shakespeare: The Merchant's contract revisited. Am J Obstet Gynecol 1989;160: 59-62) should not pass without at least a brief rebuttal; the numerous errors of fact therein would require a more extensive response beyond the scope of the available space.

It is one thing for the authors to opine that obstetricians should not own or operate a surrogate parenting agency. It is quite another for them to tell obstetricians not to provide medical services to the parties of surrogate contracts.

To begin with, I know of no surrogate parenting agency in which a physician, much less an obstetrician, is a party to a surrogate parenting contract. Surrogate parenting contracts involve an agreement with various provisions between the surrogate and the intended parents, usually husband and (infertile) wife. Physicians are justifiably involved in providing medical care of various types to these three parties: infertility evaluation of all parties, infertility counseling, referral to surrogate parenting agencies, infectious disease screening, genetic counseling, psychiatric evaluation, artificial insemination, management of infertility in the father and surrogate, in vitro fertilization (for gestational surrogates) and ovum donation,[1] and of course prenatal care of the surrogate. As the authors correctly note elsewhere,[2] dual relationships with one's patients are ethically troublesome and should be avoided, so physicians should not contaminate their medical role with their patients by adding another one as gatekeeper, administrator, or owner of a surrogate parenting agency in which these same patients have been served.

It is presumptuous, if not ridiculous, to categorically reject surrogate parenting contracts as "unethical" per se. Surrogates, no less than living organ donors, obtain a great deal of emotional gratification in their role.[3-5] The infertile couple clearly enjoys having a biologically related child to raise, but also immeasurably appreciates the surrogate's altruism. Further, >95% of surrogacy arranagements are concluded without adverse result. Physicians' attempts to "protect" potential surrogates from themselves by rejecting, boycotting, or criminalizing surrogacy are no more justifiable than prohibiting organ donation by living donors in some transplant centers.[6]

There is unfortunately a great deal of ignorance and misinformation about surrogate parenting. La Puma et al.'s oversimplistic and biased article does not advance the cause of truth about this matter and certainly does not serve the interests of their infertile patients. Rather, obstetricians should be aware of the potential benefits, as well as risks, of collaborative reproduction for all the parties involved.

Reply

To the Editors: Dr. Wettstein suggests that surrogate pregnancy should be a medical treatment, such as artificial insemination. We suggest that there is such widespread confusion about surrogacy that it is easy to miss our point.

Surrogacy is not a medical treatment. Obstetricians should not be forced to consider withdrawing, withholding, or offering surrogacy, as if it were. Surrogacy is a nonmedical process that may lure physicians into bad business arrangements and can make unwitting middlemen of obstetricians.

In regard to transplantation ethics, a fetus is not a kidney. A fetus has no duplicate; surrender of a fetus is different from donation of a kidney. Living related kidney donors can consent or refuse to donate; surrogate mothers currently have no such choice. Sanctioning "collaborative reproduction" restores the paternalism of old, making the obstetrician both deliverer and parent.

We appreciate Dr. Wettstein's comments, and we encourage other readers to avoid confusing surrogacy with medical treatment.

Can shoulder dystocia be predicted?

To the Editors: I feel that James O'Leary, MD, and Helen Leonetti, MD, have done a great disservice to their colleagues who are practicing obstetricians. In their article "Shoulder dystocia: Prevention and treatment" (Am J Obstet Gynecol 1990;162:5-9), they give the distinct impression that most if not all shoulder dystocias should be anticipated and/or predicted and thus prevented by performing abdominal delivery. They present several tables identifying prepregnancy historical risk factors, antepartum risk factors, and intrapartum risk factors. Unfortunately they do not present any scientific data to show which risk factor or combination of risk factors would provide reasonable indications for a cesarean delivery. I believe that if Dr. O'Leary and Dr. Leonetti are honest with themselves and with other readers of the Journal they will agree that to prevent one shoulder dystocia dozens of unnecessary cesarean sections with their attendant morbidity and mortality would need to be performed. Unfortunately the legal profession has access to our professional journals, and I feel that articles like this can and will be used against anyone unfortunate enough as to find himself with a severe shoulder dystocia and an injured infant. It is a rare obstetric patient indeed that does not have at least one or several of the risk factors mentioned by the authors.

Gregory L. Gimbel, MD
Department of Obstetrics and Gynecology, Parkview Memorial Hospital, Brunswick, ME 04011

Reply

To the Editors: McLeod (McLeod A. In discussion: Hopwood HG Jr. Shoulder dystocia: Fifteen years' experience in a community hospital. Am J Obstet Gynecol 1982;144:162-6) states: "that 'shoulder dystocia occurs cataclysmically' *must be* challenged; in many, if not a majority of cases, *it can and should be anticipated* [italics added]." He goes on to state: "All of these risk factors are identifiable and in most cases *should be* interpreted as a warning sign [italics added]."

Eight years later these same statements are still valid. The intent of our review article was to reemphasize the importance of risk factors for macrosomia and to outline a rational approach to dealing with the issue.

Hyperbaric oxygen therapy for air embolism complicating operative hysteroscopy

To the Editors: Baggish and Daniell (Baggish MS, Daniell JF. Death caused by air embolism associated with neodymium:yttrium-aluminum-garnet laser surgery and artificial sapphire tips. Am J Obstet Gynecol 1989;161:877-8) reported two deaths caused by air embolism complicating operative hysteroscopy with laser surgery. Hyperbaric oxygen therapy was not mentioned in their article.

Immediate therapy with hyperbaric oxygen, however, must be remembered and should be encouraged for those patients with suspected air embolism. Hyperbaric oxygen therapy, a combination of compression-recompression and hyperoxygenation, is effective in the treatment of air embolism in patients who survive the initial insult. Hyperbaric oxygen decreases intravascular bubble size (on the basis of Boyle's law) and increases the driving pressure of oxygen into tissue, and thus reduces ischemia. The time between embolism and the time of hyperbaric oxygen treatment may determine the outcome in these patients. If necessary, air transportation should be used, either via a pressurized cabin for maintaining sea level pressure or by instructing the pilot to fly as low to the ground as safely possible.[1-3]

Gynecologists performing operative hysteroscopy, with or without laser surgery, must maintain a high index of suspicion concerning air embolism when confronted with acute respiratory failure and/or focal or general neurologic deficits in an otherwise healthy

woman. A sharpened awareness about appropriately timed hyperbaric oxygen treatment may improve outcome for some patients. Early consultation with a physician skilled in hyperbaric oxygen therapy is essential. Hyperbaric consultation can be obtained without charge 24 hours a day through the Divers Alert Network, Duke University, Durham, N.C., at (919) 684-8111.

Reply

To the Editors: Dr. Tur-Kaspa's point is well taken. Unfortunately, the article published in the JOURNAL was a brief communication, and space limitations prevented us from reporting all the cases of catastrophic injury associated with the intrauterine use of artificial sapphire tips. One additional case of gas embolism (not cited in the article) was quickly recognized and the patient was transferred to a hospital equipped with a hyperbaric oxygen chamber. The patient survived but was left with a neurologic deficit.

In the two cases we reported in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY the events proceeded rapidly and cardiovascular collapse occurred with alarming speed. Whether hyperbaric oxygen could have saved those patients' lives is not known. Whether such facilities were readily available is still another question.

More important is the most direct remedy, i.e., to avoid this catastrophe by selecting other, safer modalities in the first place. Use of bare fibers and liquid media will preclude the risk of gaseous embolism.

Michael S. Baggish, MD

Department of Obstetrics and Gynecology, College of Medicine, State University of New York Health Science Center, 750 East Adams St., Syracuse, NY 13210

Fluid cooling of artificial sapphire tips of laser

To the Editors: Drs. Baggish and Daniell state in their article (Baggish MS, Daniell JF. Death caused by air embolism associated with neodymium:yttrium-aluminum-garnet laser surgery and artificial sapphire tips. AM J OBSTET GYNECOL 1989;161:877-8) that "... the use of sapphire tips for intrauterine laser surgery is associated with grave hazards for the patient." This is not a valid conclusion.

What they should have concluded and what laser manufacturers caution against is that gas, because of the high flow rate required, should not be used to cool the tips in the uterine cavity. There is no hazard, theoretical or demonstrated, if a fluid is used to cool the tips.

Franklin D. Loffer, MD

Gynecological Associates, Ltd., 3410 North 4th Ave., Phoenix, AZ 85013

Reply

To the Editors: In response to Dr. Loffer we offer the following:

The artificial sapphire tip may be applied safely for intrauterine surgery with two provisos: (1) Liquid cooling is utilized; (2) there is no chance for mistakenly instilling gas.

The manufacturer has the responsibility to design a fail-safe system to accept *only liquid* as the cooling mechanism. Unfortunately, coaxial fibers fitted with sapphire tips can optionally be cooled with gas. A recent article[1] published in *Contemporary Ob/Gyn* documents that gas cooling is still an alternative. Speaking at a laser seminar as recently as January 26, 1990, a recognized enthusiast of the sapphire tip contact technique presented data about laser laparoscopy and advocated cooling the sapphire probe with carbon dioxide gas at a flow rate of 400 ml/min. Although this flow rate may be interpreted as better than the 1 to 2 L/min recommendation cited above,[1] nevertheless it is unsafe when viewed in the context of a device directly in contact with tissues (blood vessels). No data whatsoever have been presented in the literature to indicate that gaseous delivery is safe under these circumstances.

In regard to intrauterine surgery the use of sapphire tips is unwarranted for ablation since this operation is better accomplished with a bare fiber. Septa and adhesions may be cut effectively with scissors or alternatively by argon or KTP 532 laser–delivered fibers. Recently bare extruded cutting fibers for use with any neodymium:yttrium-aluminum-garnet laser have been introduced. The extruded Nd:YAG fiber is very safe, concentrates Nd:YAG laser energy to a fine focal point, and best of all requires no cooling.

The Nd:YAG laser and the Nd:YAG contact laser accounted for the largest number of laser incidents, 37%, according to a recent Food and Drug Administration report.[2] This sobering testimony adds further support to our conclusions. Until absolute assurance can be provided that gas (air, nitrogen, or carbon dioxide) cannot gain entry into the artificial sapphire tip cooling mechanism, the system should be considered dangerous for intrauterine surgery and for that matter any other vascular site.

Survival in a fetus with sacrococcygeal teratoma and hydrops

To the Editors: Langer et al. (Langer JC, Harrison MR, Schmidt KG, et al. Fetal hydrops and death from sacrococcygeal teratoma: Rationale for fetal surgery. AM J OBSTET GYNECOL 1989;160:1145-50) reported on three fetuses with sacrococcygeal teratoma and hydrops, a combination of findings with a high rate of perinatal death.[1] One of the three underwent resection of the tumor at 24 weeks and was returned to the uterus. Hydrops resolved and cardiac output decreased, based on echocardiographic and Doppler measurements. From their experience the authors recommended that fetal surgery may prove to be the most effective treatment for fetuses with sacrococcygeal teratoma and hydrops.

We recently treated two newborn infants with sacrococcygeal teratoma and hydrops without fetal surgery, and both survived. Detailed descriptions are to be published.[2] They were born at 30 and 33 weeks and thus were more mature than those in the study of Langer et al. The latter infant had severe respiratory insufficiency despite maximal ventilatory support and vasodilator infusions, and oliguric acute renal failure. Removal of the tumor on the second day of life led to an immediate improvement in respiratory function, with PaO_2 increasing from 48 mm Hg with use of 100% oxygen to 253 to 357 mm Hg intraoperatively. This allowed a decrease in the FIO_2 to 0.45 by the first postoperative day and extubation on the tenth day. Renal function returned in a pattern typical of recovery from acute tubular necrosis. The former case, delivered at 30 weeks, also had respiratory insufficiency that improved after surgery. Both infants are presently alive and without neurologic, pulmonary, or renal sequelae.

We therefore agree with the assertion of Langer et al. that cardiopulmonary physiology improves after tumor resection. However, affected infants born as early as 30 weeks can survive without intrauterine tumor removal. Allowing gestation (and thus fetal lung maturation) to continue constitutes an alternative to fetal surgery for affected fetuses closer to term (28 to 30 weeks). However, the combination of a sacrococcygeal teratoma and hydrops reflects severe physiologic instability; fetal death is an ever-present risk.[1] A delay in tumor resection to allow further lung maturation may result in stillbirth. One of the fetuses of Langer et al. died the day before planned fetal surgery; we were able to delay 3 weeks in a fetus of later gestation (21 vs 30 weeks). If fetal surgery has a role in sacrococcygeal teratoma, we suggest that it may be indicated in fetuses with hydrops detected before 28 weeks.

Response declined

Ascertainment bias in diabetic outcome data

To the Editors: Drs. Damm and Molsted-Petersen have retrospectively studied a group of infants born to mothers with diabetes in an effort to determine a trend in the rate of congenital malformation (Damm P, Mølsted-Petersen L. Significant decrease in congenital malformation in newborn infants of an unselected population of diabetic women. AM J OBSTET GYNECOL 1989; 161:1163-7). They found that this rate has decreased, particularly over the last 5 years, and ascribe this improvement in outcome to better control of maternal diabetes. However, ascertainment bias may have seriously compromised their findings. The study group was identified through the records of infants born after 26 weeks' gestation. Therefore if a mother with diabetes was found to have a fetus with a congenital anomaly in the second trimester and elected to have a termination, this case would be missed according to the methodology described by the authors. Prenatal diagnostic procedures, particularly ultrasonography and maternal serum α-fetoprotein testing, have become more widely used over the time period under study, and the sensitivity and accuracy of ultrasound examination for congenital anomalies has improved significantly.

It appears possible that the authors have documented the enlarging role of prenatal diagnosis in the care of diabetic women and the subsequent termination of anomalous fetuses. The authors state that the "decline in congenital malformations was not due to an increased rate of induced abortions." However, no data are presented to support this statement. Indeed, a change in the overall rate of induced abortion would not necessarily be expected because improved diagnostic techniques have allowed for more selective use of termination.

The authors may certainly conclude from their study that the risk of delivering a child with a congenital defect has decreased in their sample. However, the question remains as to whether this finding results from a decreased frequency of anomalies because of better metabolic control or from improved detection because of advances in second-trimester fetal diagnosis.

Jack FitzSimmons, MD, and Susan Davidson, MD

Department of Obstetrics and Gynecology, University of Wisconsin–Madison Medical School, H4/654 Clinical Science Center, 600 Highland Ave., Madison, WI 53792

Reply

To the Editors: We welcome the opportunity to respond to the relevant comments of Drs. FitzSimmons and Davidson. The primary goal of our study was to investigate the incidence of congenital malformations in infants delivered by mothers with diabetes. We therefore decided only to consider infants born after 26 weeks' gestation. Drs. FitzSimmons and Davidson speculate that this cutoff point leads us to miss malformations diagnosed by antenatal screening and followed by termination in the second trimester. Furthermore, they hypothesize that the demonstrated decline in congenital malformations could be caused by better antenatal

screening followed by elective abortion rather than improved maternal diabetic control.

The outcome of all diabetic pregnancies (deliveries and abortions) in our hospital has been registered consecutively in the entire study period, especially with regard to malformations. As described in our article the abortion rate has been nearly constant over the years; in fact, a significant decrease in induced abortion from 12.8% to 5.6% was observed from the period 1977 through 1981 to 1982 through 1986 in White Classes D and F.

Since 1978 antenatal screening for malformations has been done in our department by ultrasound and amniotic fluid α-fetoprotein determination, and since 1982 serum α-fetoprotein determination also has been included. Only one single diabetic pregnancy since 1978 has been terminated because of a malformation diagnosed by second-trimester screening. This was a case of anencephaly diagnosed by ultrasonography and α-fetoprotein; the pregnancy was terminated in the seventeenth week of gestation. The mother was in White Class F with diabetic nephropathy and proliferative retinopathy; preconceptionally she had been strongly advised against pregnancy. This one case will obviously not change the message of the study, namely, that a significant decrease in congenital malformations in newborn infants of mothers with insulin-dependent diabetes has occurred in the period 1982 to 1986 in comparison with the previous 5-year periods. The cause for this decrease in congenital malformation is as previously argued in our article and is probably multifactorial. Our data indicate that the decline in congenital malformations only to a minor degree is caused by improved antenatal screening. We therefore still believe that the decline in congenital malformations is mainly the result of the following two factors: a high frequency of planned pregnancy, which is essential in women with diabetes to reduce the frequency of congenital malformations in the outcome of pregnancy and overall improved diabetes care and metabolic control in young women with diabetes in Denmark during the 1980s.

Rapid determination of fetal sex

To the Editors: I would like to comment on the article by Pinckert et al. (Pinckert TL, Lebo RV, Golbus MS. Rapid determination of fetal sex by deoxyribonucleic acid amplification of Y chromosome–specific sequences. Am J Obstet Gynecol 1989;161:693-8). I disagree with the conclusion that this technique-technology "appears to be a reliable method to rapidly determine fetal sex that also can be used diagnostically to identify translocated Y-chromosomal material."

With three false-positive "male" results in 35 fetal sex determinations and approximately a 10% error rate, this is hardly accurate enough for "screening." Quite clearly the problems arise in relying solely on deoxyribonucleic acid study results and not deoxyribonucleic acid in conjunction with "some other sex determination technique."

It has been documented that visualization of the fetal external genitalia in early pregnancy by Fetal Anatomic Sex Assignment (Fetal Anatomic Sex Assignment is a Service Mark of John D. Stephens, MD, and is registered in U.S. Patent and Trademark Office, July 1990) is essentially 100% accurate and even has the capability of "correcting" laboratory errors.[1]

It has also been subsequently shown (and I believe that the case of the 15p+ de novo Y translocation has previously been "published"[2]). In this case ultrasound revealed female external genitalia followed by amniocytes, which showed 46,XX,15p+. Q and C banding indicates that this abnormal 15 chromosome is possibly a t(Y;15). Both parents were shown to have normal karyotypes. A repeat ultrasonogram at 20 weeks again showed female external genitalia. This implied de novo Y;15 translocation with only Yq, mainly heterochromatic area involvement. The couple elected to continue the pregnancy. After delivery skin biopsy showed a positive deoxyribonucleic acid Y-chromosome–specific probe in an otherwise "normal" female infant. This was also repeated and confirmed at The University of Gainesville in Florida (personal communication).

The other two cases (cases 1 and 3) merit discussion because in those cases "reliance" on the deoxyribonucleic acid Y probe as a screening test would have been incorrect in case 3 and probably would have correctly diagnosed male sex but would have missed the 45,X cell line. In case 3 the patient was 41 years old at the time of amniocentesis, which revealed female external genitalia. The amniocytes showed 46,XY. The infant was subsequently born and was confirmed to have testicular feminization syndrome. In case 1 ultrasonography revealed male external genitalia and the amniocytes showed 45,XO/46,XY; although all such information of normal male external genitalia was given during counseling, the couple terminated the pregnancy. The mosaic karyotype was confirmed in fetal skin.

The most recent "experience" with confirmation of ultrasonography, chromosomes, and deoxyribonucleic acid Y probe (performed at The University of California Medical Center, San Francisco) was a case of 45,X/46,X dicentric Y chromosome; the fetus had female external genitalia on the ultrasonogram and a positive deoxyribonucleic acid Y probe. The couple elected to terminate the pregnancy. Pathologic study confirmed female external genitalia, and mosaic karyotype was also subsequently reconfirmed.

Therefore I disagree with the conclusions made by Pinckert et al.: "These characteristics make polymerase chain reaction sex testing an ideal tool for prenatal studies."

The only value of this technology would be in cases in which the chromosome studies have already been performed and there is sex chromosome mosaicism; the value lies in investigating and identifying translocated Y-chromosomal material. The major usefulness in such cases would be for discussion regarding the recommendation that gonads be removed in phenotypic females with Y-chromosomal material.

Visualization of the fetal external genitalia in early pregnancy, which can be achieved at 12 weeks for males and 14 weeks for females, is more reliable and is the more "ideal" tool for prenatal studies, particularly as a noninvasive tool for genetic counseling when there is a family history of X-linked conditions and when the couple wishes to avoid invasive techniques.

Reply

To the Editors: Dr. Stephens' letter contains a few points that require a response. First, the three false-positive results were obtained with the dot blot method and not the polymerase chain reaction method; that was the point of the article. Second, the Y;15 translocation reported in our article is not Dr. Stephens' case, although we have studied such a case for him. Third, the two paragraphs regarding his reported abstract are not pertinent; if he wishes to have his work reviewed, he should submit it for peer review. Fourth, the recent case described by Dr. Stephens does serve to remind the reader that the test is designed to determine the presence or absence of a deoxyribonucleic acid fragment and not the genital sex. The fetal genital sex was determined by ultrasonography and we assume Dr. Stephens approves of this. Finally, the remaining sections of the letter are advertisements for Dr. Stephens' patented ultrasonographic determinations of fetal sex and do not require a response.

Use of the T-ACE questions to detect risk-drinking

To the Editors: Sokol et al. (Sokol RJ, Martier SS, Ager JW. The T-ACE questions: practical prenatal detection of risk-drinking. Am J Obstet Gynecol 1989;160: 863-70) studied a technique to identify pregnant "risk-drinkers" for whom targeting unique interventions might be appropriate. However, we do not think their instrument succeeds as a screening tool.

Two issues are relevant to screening for maternal alcohol use. The first is whether any alcohol consumption during pregnancy is acceptable. The threshold for adverse outcomes from maternal alcohol consumption is not known. A linear rather than threshold model of toxicity best explains behavior abnormalities caused by prenatal alcohol exposure.[1] The entire maternal intake range before pregnancy was correlated with both Apgar score and rate of spontaneous abortion.[2] Although some adverse outcomes may require high prenatal exposures, lower levels also may have detrimental consequences. The authors used a history of ≥1 ounce of absolute alcohol per day as their threshold for risk drinking. The T-ACE questions may be insensitive to lower, but clinically important, levels of drinking.

A second issue is underreporting of alcohol consumption during pregnancy.[3] The methods used by the authors to quantify alcohol consumption are susceptible to this bias. The item in the T-ACE instrument that had the strongest association with alcohol consumption was the question about tolerance. Patients who reported tolerance may be those who discount the importance of alcohol use. They may be a group more likely to report their intake accurately and are less prone to the underreporting bias. Thus the T-ACE instrument may be less sensitive than this study suggested for detecting those women who underreport risk-drinking.

A score of 2 or more on the T-ACE questions suggested a high level of alcohol consumption. A lower score should not be interpreted as an indication that counseling and follow-up about alcohol use are not indicated. Rather than a "Papanicolaou smear," as the authors suggest, the questions are more analogous to an electrocardiogram. A "normal" test does not exclude significant problems.

Reply

To the Editor: The utility of our T-ACE questions as a simple screening device to identify women who drink enough alcohol to potentially damage their unborn offspring is questioned in the above letter on two bases.

First, it is speculated that the T-ACE questions may be insensitive to low, but clinically important, levels of drinking. However, screening for "any use" with T-ACE is not the issue. Rather, we recommend asking all patients whether they ever drink any alcoholic beverages. Heavy drinkers rarely have a level of denial leading to a negative answer to this question and occasional-to-moderate drinkers uniformly answer positively. The T-ACE questions are then asked of all drinkers, and drinking patterns are explored fully in those who are T-ACE positive. Finally, we recommend abstinence during pregnancy to all women who do drink, although we interpret the literature to indicate no detectable clin-

ically important impact from an occasional drink. Even with this strategy, it can be anticipated that many embryos, possibly the majority (perhaps 70% of American reproductive-age women are not abstinent), have some alcohol exposure because many pregnancies are unplanned. In the real world of patient care, we most surely would not want to recommend pregnancy interruption to a woman who presents for a pregnancy test and indicates that she had a few drinks before pregnancy recognition.

The usefulness of T-ACE as a screening test does not rest on whether there is a threshold. Rather, it is based on a well-documented dose-response phenomenon—more alcohol exposure, greater damage.[1] The goal is to identify the heavy drinker. This is the most cost-effective approach to the goal of preventing alcohol-related birth defects. The problem, of course, is that very few women who drink heavily are currently identified by obstetrician-gynecologists. We believe that T-ACE can help identify them.

The second objection is that underreporting may have biased the results of our study. Underreporting surely occurs; indeed, it was our research group that documented and defined the extent of this problem during pregnancy. The only significant determinant of an increase in underreporting was found to be evidence of problem drinking (high Michigan Alcoholism Screening Test [MAST] score), probably mediated by psychologic denial.[2, 3] In the study under discussion, T-ACE positivity was associated with MAST positivity; thus reported tolerance would not be associated with overreporting, as speculated in the letter. T-ACE *will* miss some at-risk pregnancies, at least the 30% we reported, but it can be expected to detect a substantial fraction of the heavier drinkers, most of whom are now unidentified. If, indeed, the prevalence of heavy drinkers were higher, the positive predictive value and false-positive rate of T-ACE would be improved. The sensitivity and specificity would not be affected. A lower cutoff point would result in a clinically unacceptable false-positive rate.

We agree that a negative T-ACE result does not rule out "significant problems." However, it does make them much less likely. The real question is whether T-ACE can detect not only at-risk pregnancies, but also affected offspring. We are now studying that crucial question. Preliminary results indicate that T-ACE negativity is in fact associated with a significant decrement in sonographically detectable anomalies, compared with the rate in T-ACE–positive pregnancies.

We believe that our results clearly indicate that screening with T-ACE is clinically useful.

Cervical cancer: Role for progesterone during pregnancy and contraception?

To the Editors: Epidemologists agree that etiologic factors in cervical cancer are complex and multiple. Factors mentioned most recently in connection with this tumor include cigarette smoking and oral contraception, which paradoxically are almost nonexistent in rural areas of developing countries where the tumor is most common. Sexual behavior is traditionally accepted to underlie all theories of cervical neoplasia with early age of onset of coitus or multiple sexual partners thought to be most significant. The role of reproductive factors on the other hand has remained equivocal, often relegated to a position of surrogacy to sexuality.[1] This view has persisted despite several excellent studies from developing countries that show multiparity to be an important independent risk factor.[2, 3] Further support of this view has recently emerged from new epidemiologic studies in both developed and developing countries that show a strong linkage between multiparity and cervical neoplasia.[4, 5] It is now thought that a major factor in this linkage may be progesterone rather than trauma or infection per se. This hormone is known to be immunosuppressive.

Strengthening the case for progesterone are recent studies in molecular biology that have found an interaction between progesterone and human papillomavirus (HPV). It is reported that HPV 16 encodes a protein mapped in the region of E 6 and E 7 open reading frames that will cooperate with activated ras oncogene to transform primary cells.[6] The long control region of HPV 16 is also reported to contain a deoxyribonucleic acid sequence that mediates response to both progesterone and glucocorticoids thus increasing E 6 and E 7 transcription.[7] In pregnancy progesterone enhances HPV gene expression, giving rise to increased viral copy number and increased multiplication of virus-transformed cells.[8]

Increased prevalence of HPV in pregnancy has been confirmed[9] and there are also several reports that claim faster progression of cervical cancer in pregnancy.[10] Although studies of the effect of depot medroxyprogesterone acetate on cervical neoplasia give inconclusive results, there is the question of the critical levels of progesterone required to stimulate change and whether such concentrations are obtainable through currently available progesterone contraceptives.

The possibility of primary prevention of cervical cancer through family planning is an attractive one and would be ideal for developing countries, many of which are involved in extensive family planning programs. Combination of secondary cancer preventive activities

with family planning services would also be ideal. However, an important question is whether some of the family planning devices may themselves negate the desired effect by promoting neoplastic change. It is realized that progesterone-containing contraceptives are the most widely used agents in developing countries and newer progesterone-containing vaginal and cervical devises are currently being introduced.[11] The effect of increased local concentration of progesterone because of such devises on viral transcription in the cervix should be a decent scientific concern. Recent reports that HPV 16 and 18 are highly prevalent in rural women[12, 13] add further relevance to this concern.

Breast diagnostics in clinical gynecology

To the Editors: The article by Dr. Gleicher (Gleicher N. Breast disease programs in obstetrics and gynecology: A plea for training in mammography. Am J Obstet Gynecol 1989;161:267-70) addresses what I hope will be one of the most significant directions for training gynecology specialists in the near future. Combining primary gynecology and quality breast diagnostics will dramatically increase the compliance of American women with current mammography recommendations. I have evidenced this increased compliance in my practice with the combination as described in this article.

As a practicing gynecologist, I have completed Dr. Tabar's levels I, II, and III advanced courses in breast diagnostics. In addition, I will be spending 2 weeks in Sweden studying with Dr. Tabar in a unique one-on-one training experience. As a result of my training, I have incorporated breast diagnostics into my practice; I am finding small occult cancers that previously I was missing on physical examination alone. My patients have the benefits of being evaluated by mammography and, when indicated, dedicated breast ultrasonography, fine-needle aspiration biopsy, and needle localization for use with surgical biopsy. These combinations of services often eliminate the need for further diagnostic workup. Providing these services to my patients only enhances the already established primary care relationship between myself and my patients. Patients like being able to have their annual examinations and their mammograms done in one location and under the direction of one central primary care physician. The result is a more responsible and comprehensive continuity of care for these women. Patients leave the office knowing the results of their mammograms, and they are educated and advised about any further diagnostic workup that might be necessary.

Because of our access to large numbers of women, I believe that to effectively change the death rate from breast cancer we as gynecologists must ultimately accept the responsibility for women's breast care. I clearly understand the obstacles that face gynecologists in undertaking this endeavor. Establishing an acceptance within the medical community of quality mammography interpretation by the gynecologist would be a major step forward in current breast care standards. To establish this acceptance, the American College of Obstetricians and Gynecologists must aggressively pursue expert training for its physicians before specialty certification, and then be committed to educating the rest of the medical community on the value and importance of this new approach. I have witnessed these benefits in my own practice, and I am confident that as a gynecologist, I have and will continue to effectively increase compliance to life-saving mammography.

The complex nature of egg transport through the oviduct

To the Editors: I read with special interest the article by Pulkkinen and Jaakkola (Pulkkinen MO, Jaakkola U-M. Low serum progesterone levels and tubal dysfunction—A possible cause of ectopic pregnancy. AM J OBSTET GYNECOL 1989;161:934-7) in which the authors demonstrated low prouterine gradients of electrical activity at the fimbrial end and weak propulsive forces in terms of electrical bursts and inactive areas in patients with low progesterone levels. They speculated that these phenomena were related to the higher incidence of ectopic pregnancies in patients with progesterone deficiency.

The definite forces of egg transport, however, may not depend on muscle contractions at all, as Halbert et al.[1] demonstrated with the complete blockage of muscle activity in an in vivo model by infusion of isoproterenol. Totally against expectations, the transport of stained cumulus egg masses was of even shorter total duration. As a consequence, the importance of the ciliary apparatus in effecting ovum progress was emphasized.

However, as shown in a woman with Kartagener's syndrome,[2] the ciliary movement also probably is not essential.

A recently advanced hypothesis includes special arterial cushions around the intramural part of the tube as an arterial, pulse-triggered pump for egg transport.[3]

In general, the propulsive mechanism seems to be of very complex nature and the occurrence of tubal implantation of the conceptus may not be explained by certain inactive areas of muscle activity leading to partially slower egg transport through the oviduct. This is further assisted by the fact that in a substantial group of tubal pregnancies (23.8%[4] to 50%[5]) the corpus luteum is found on the contralateral ovary. In one possible explanation of this fact, the ovum is released into the cul-de-sac, and pickup by the contralateral tube might be variably delayed, thus leading to implantation in a normally active tube. The other mechanism as to how an egg can enter the contralateral tube is via the uterus, and this might even depend on higher propulsive forces to reach the implantation site.

Ch. Egarter, MD

To the Editors: We concur with Dr. Egarter when he says that the propulsive mechanism in the oviduct is complex in nature. As evidence against the role of the smooth muscle in ovum transport, Dr. Egarter cites the case where, although muscle activity was completely blocked by isoproterenol, there was nevertheless rapid ovum transport. A different complexion is put on the matter if we consider two factors: (1) Dr. Halbert and his co-workers studied only the ampulla, not the isthmus, and (2) isoproterenol is excitatory to cilia.

The smooth muscle plays a role in the transport of ovum surrogates through the ampulla.[1] The number of ciliated cells in the isthmus is small and ciliary currents may not be exclusively in the uterine direction.[2] The contractions of a thick muscle layer are apparently significant for the propulsive mechanism in this part of the oviduct, partly because the contractility of the smooth muscle changes the intraluminal pressure that moves the luminal contents.[3] Contractility is seen as electrical activity. With the same method used as that in the oviduct, it has been shown that there is a relation between luminal transport and the spread of electrical activity, also in the epididymal duct.[4]

The article by Brokelmann, about arterial cushions in the oviduct, to which Dr. Egarter also refers, contains no information about ovum transport.

On the face of it, the mechanism suggested by Dr. Egarter, i.e., that the ovum first enters the uterus through one oviduct and is then propelled to the other, seems unlikely and is not supported by experimental findings (except in vitro fertilization). The mechanisms by which ectopic pregnancy may develop include, among other things, a large passenger ovum (possibly from the contralateral ovary, as suggested by Dr. Egarter), impaired ciliary activity in the ampulla, postinfectious anatomic changes, and, especially in the isthmus, dysfunctional smooth muscle. As we have suggested, a possible parameter would be a low progesterone level. In our detailed analysis it was found that sine wave activity in the oviduct had the best correlation with serum progesterone level, and it is known that sine

wave electrical activity also correlates with nonpropulsion in the intestines.[5]

Appropriate screening tests

To the Editors: Although I was impressed by the skill in which Dr. Chervenak and associates make an argument for the routine offering of medically unindicated ultrasonography to pregnant women (Chervenak FA, McCullough LB, Chervenak JL. Prenatal informed consent for sonogram: an indication for obstetric ultrasonography. Am J Obstet Gynecol 1989;161:857-60), there are some significant flaws in their logic that I feel must be pointed out. Without quoting actual data, the authors state "Established benefits currently outweigh harms, because the harms of false-positive and false-negative diagnosis can be minimized and the potential harms described by Kremkau may not ever be established." Although it is true that falsely abnormal results can be minimized in expert hands, there is little question that, when the routine offering of medically unindicated ultrasonograms becomes part of standard practice, most obstetric ultrasonography would be performed with insufficient expertise to obviate falsely abnormal results.

The authors further state that the most that can currently be reasonably assumed is that some theoretical harms might outweigh some of the benefits. They correctly point out that there is no way to know reliably whether all of the harms will eventually outweigh all of the benefits, and they state that they believe that it's unlikely that a randomized trial will be performed, or that if performed that conclusive results would result. This seems to be an excellent argument against any clear benefit attributable to routine ultrasonography. The assumption that obstetricians will provide appropriate counseling to their patients so that they can make a correct informed decision is not only not supported, but the information that obstetricians might use in providing that counseling is nowhere suggested. For a woman to make a correct informed consent about obtaining an unindicated ultrasonogram, it would be necessary for her to know the utility of that ultrasonogram with respect to her health and the health of her infant and the potential cost to her and her infant of a falsely abnormal or a falsely normal result.

In the current malpractice crisis a likely result of the routine offering of medically unindicated ultrasonograms would not be the provision of informal office ultrasonograms for a "fun look at the baby" but much more likely would be level 2 ultrasonograms performed by trained sonologists. Certainly, if studies are going to be done, this is how they are best done; however, the cost to the medical care system would be significant. At a time when many areas are struggling to increase access to care by extending Medicaid to women with incomes up to 185% of the federal poverty level, it seems onerous to add a medically unindicated diagnostic test.

David A. Nagey, MD, PhD
Division of Maternal-Fetal Medicine, University of Maryland, 22 South Greene St., Baltimore, MD 21201

Reply

To the Editors: We appreciate Dr. Nagey's thoughtful comments and want to respond directly to his charge that "there are some significant flaws" in the logic of argument for prenatal informed consent for sonogram. Dr. Nagey's claim is that our argument is, in the technical language of logic, invalid. In particular, he claims that a conclusion other than the one that we draw follows from our premises about the goods and harms of routine ultrasound. Dr. Nagey thinks that the conclusion should be that there is no "clear benefit attributable to routine ultrasonography." This conclusion cannot follow from our premises. It is a well-known principle of logical reasoning that it is impossible to derive from a premise a conclusion that is its contradiction. Moreover, it contradicts one of the premises, namely, that there are already established clear-cut benefits to routine ultrasonography (e.g., the detection of unsuspected fetal anomalies at a time during which the pregnant woman may elect changes in her obstetric management.[1, 2] It is unfortunate that there is such a widespread misconception in the obstetric community about this certain, not uncertain, value of routine ultrasonography. What does follow from our premises is that there is no clear-cut balancing of the goods and harms of routine ultrasonography. This conclusion supports a woman's choice in this matter, namely, prenatal informed consent for sonogram.

In adition to criticizing the "logic" of our argument, Nagey makes other comments we wish to address. First, he is correct in his concern about "insufficient expertise" in the performance of routine ultrasonography, a concern that we already expressed in our article. Second, his suggestions for the counseling of pregnant women constitute a useful enhancement of prenatal informed consent for sonogram. Third, we agree that increased cost may be a significant factor. However, as

we point out in our article, the ethical significance of that potential increased cost must be addressed in the larger context of the formation of public policy in the democratic process. For example, it is possible that the increased expenditure for routine ultrasonography would reduce by a greater amount other medical expenses, such as neonatal costs, and thus be cost beneficial to society.

Breast disease programs and mammography training

To the Editors: We are concerned about a conclusion in an article in the August 1989 issue of the JOURNAL (Gleicher N. Breast disease programs in obstetrics and gynecology: A plea for training in mammography. AM J OBSTET GYNECOL 1989;161:267-70). Dr. Gleicher concluded that gynecologists, to become interested in breast disease as part of their care of women, should undertake the performance and interpretation of mammograms.

We concur with the conclusion that gynecologists should become knowledgeable about the diagnosis and management of breast disease as a part of their residency and continuing medical education. In the programs of the American Cancer Society and the joint activities of the American College of Obstetricians and Gynecologists and the American College of Radiology, we have urged strongly that more attention be given to breast cancer, a disease that will strike one American woman in 10 during her lifetime.

Indeed, all our statements about breast cancer have emphasized that proper breast care begins with regular visits to a physician for physical examinations, followed at the appropriate age by periodic mammograms. It was the failure of gynecologists and other primary care physicians to uniformly use available breast cancer detection procedures that led the American Cancer Society, the National Cancer Institute, and many medical societies to embrace the concept of mammography as a screening procedure. The "walk-in" concept of screening mammography is less desirable than the standard medical approach, but it will reach many women who lack access to periodic examinations and mammography on any other basis.

The incorporation of mammograms into regular examinations of women is an end much to be desired. Making such examinations available in a timely and convenient manner has had the attention of many clinicians in several interested medical specialties. The correlation of history, physical findings, and the results of the mammogram are ideally made by the primary physician after consultation with colleagues.

However, we must suggest strongly that Gleicher's assertions that gynecologists can "pick up the art of mammography" by short courses or informal training would detract from the achievement of our shared objective and from the overall quality of care now afforded in most American cities.

Many of us who have been involved for three decades in the development and proliferation of modern mammography have overcome a series of problems. These include development of a standard technique to produce a valid image, constant attention to radiation safety, a concern with repeated examinations, and the acquisition of the visual acuity needed to detect and identify early radiologic signs of breast malignancy. After all these hurdles, it remains fair to observe that good mammography is most difficult to perform and interpret.

For more than a decade instruction in mammography has been part of the residency programs for diagnostic radiologists. A similar emphasis is incorporated in the training programs for radiographers. Beyond the formal training, some radiologists have subspecialized in mammography, just as others have concentrated on other areas. A vigorous set of continuing medical education opportunities provide upgrading for radiologists and radiographers about mammography. These programs are predicated on the basic skills acquired by radiologists in roentgen interpretation, radiation safety, and imaging technique. For Gleicher to suggest that gynecologists can detract from their own excellent and demanding residency programs to acquire a level of skill in a single (but intensely demanding) imaging procedure reflects a failure to appreciate the difficulties therein. For a radiologist to assume that his interest and skill in mammography, plus a few lectures or weekend courses, would qualify him to practice gynecology would be equally indefensible.

In recent years many of us in medicine have been part of a ground swell movement to make both clinical and screening mammography available to American women. Radiologists have been urged to provide screening programs in their hospital departments, offices, clinics, mobile services, and other sites. They have been urged, and even mandated by the pending Medicare screening coverage rules, to reduce the fee for screening to a figure well below prevailing rates for clinical mammography. They have been urged to work with gynecologists and other colleagues to establish a referral mechanism for women with positive findings on screening examinations. The American College of Obstetricians and Gynecologists has urged its members to become part of the breast care team with surgeons, pathologists, and other physicians.

We applaud Dr. Gleicher for his premise that gynecologists should learn more about breast disease and take a primary role in breast care. We renew our offer to work with The American College of Obstetricians and Gynecologists and with others to achieve that end, but we differ sharply with his conclusion that a gynecologist can and should become a proficient mammographer by brief and casual study.

Gerald D. Dodd, MD, and Robert McLelland, MD
American College of Radiology, 1891 Preston White Dr., Reston, VA 22091

Reply

To the Editors: I am pleased to respond to the communication by Drs. Dodd and McLelland in reference to my article. At the same time, I am distressed about the obvious misrepresentation of my conclusions by these representatives of the American College of Radiology. I do not believe that my Clinical Opinion article ever suggested that gynecologists could or should "pick up the art of mammography by short courses of informal training." In fact, my own experience, also delineated in my article, was based on a rather extensive training process that involved didactic training as well as the attendance of courses which, in turn, were geared toward progressively increasing knowledge and reading capabilities. Most important, however, the entire program was based on a mandatory "double reading" process by two physicians. Since its inception this program always involved both a gynecologist and a radiologist within the framework of a multidisciplinary approach, which also included a surgeon.

Although the efforts of the radiology community over three decades in popularizing and improving mammography are applauded, it must be acknowledged that radiologists have so far been unable to make mammography the Papanicolaou smear of the breast. At present only an inadequately low percentage of women have entered mammography screening programs in accordance with recommendations by the authoritative bodies as Drs. Dodd and McLelland acknowledge in their letter. To blame this fact on gynecologists and other primary care physicians, as they do in their communication, is at best unfair and at worst uninformed. Gynecologists (and other primary care physicians as well) have succeeded in integrating other aspects of preventive care into their practices quite successfully. Papanicolaou smear screening is only one example. The same cannot be said for the mammography effort, mounted by the radiology community. In fact, it may be argued that this failure directly relates to who performs mammography. As stated in my article, patient convenience as well as cost considerations favor a "one-stop" annual checkup for each woman. What makes more sense than to offer every woman over age 40 a mammogram at the same time as she receives her annual physical, pelvic examination, and Papanicolaou smear? The breast is a reproductive organ, and gynecologists perform more breast examinations and diagnose more cases of breast cancer than any other specialty.

Laudably, Drs. Dodd and McLelland appear to fully support an integrated diagnostic approach toward women's health care. Why then do they oppose such an approach in the gynecologist's office? How many radiologists perform breast examinations at time of mammography? Gynecologists do.

However, the emphasis should not lie with *who* performs mammography. There is nothing predetermined to suggest that only radiologists can perform high-quality mammography. Similar arguments were heard from the radiology community when obstetricians and gynecologists started performing ultrasound scans. Today it is accepted by both communities that excellence can be found in both specialties. Although the amount of ultrasound training in obstetrics and gynecology residency programs still varies greatly, the same can be said about radiology training programs, especially in reference to obstetrics and gynecology ultrasound. I am sure that similar differences in extent and quality of training also exist in mammography training programs. Laszlo Tabar, arguably the most experienced mammographer in the world today, emphasizes this point repeatedly in his courses, which are largely attended by practicing radiologists but are open to interested gynecologists. In these superior exercises, Tabar also repeatedly makes the point that *nobody* is perfect in reading mammography films and strongly urges all mammography centers to double read *every* film.

I am puzzled then about alleged quality concerns, expressed by Drs. Dodd and McLelland in reference to a program like ours that has used a double-reading system since its inception, at a time when the majority of mammography programs administered by radiologists do not. Moreover, let us acknowledge a few additional facts. (1) Most mammograms in this country are *not* read by radiologists specializing in mammography. In fact, very few such specialists practice in this country (in contrast to Europe). (2) Mammography is among the least desired assignments in most radiology units. Only too often this responsibility falls on the most junior and least experienced individual and is passed on at the earliest opportunity.

I and other members of our specialty applaud the willingness of the American College of Radiology to engage in a dialogue with our community. Our own departmental interest in mammography was spurred by the recognition that we as gynecologists cannot actively engage in the management of breast disease without knowledge of mammography. We therefore maintain our belief that gynecologists who manage breast problems require mammography knowledge. Obviously, this does not automatically suggest that every gynecologist with minimal mammography knowledge should read films. We require ultrasound training in our obstetrics and gynecology residency programs but not all graduating residents read their own scans. We would like to urge our radiology colleagues to accept that some

gynecologists may choose to develop adequate expertise to read their own mammography films.

This issue should not be considered a turf battle between our two disciplines. Most gynecologists are more than horrified by their already existing medical liability situations and will not wish to expand it even further into the legally volatile diagnosis of breast cancer. At the same time, I cannot understand the apparent sensitivities expressed in the letter by Drs. Dodd and McLelland. Radiologists have no hesitation to enter practice areas of other specialties when they believe that a patient benefit can be obtained. When this recently happened in an area of gynecology,[1] our community welcomed our radiology colleagues with open arms.[2] We should expect the same.

Vaginal birth after cesarean section: An appraisal of the reappraisal

To the Editors: Drs. Yetman and Nolan recently reported on attempted vaginal birth after cesarean section in 224 women (Yetman TJ, Nolan TE. Vaginal birth after cesarean section: a reappraisal of risk. AM J OBSTET GYNECOL 1989;161:1119-23). I am concerned that some of the conclusions reached in this study may not be supported by the data presented.

The authors concluded that "women who consider vaginal birth after cesarean section should be counseled with regard to the increased risk of perineal trauma." This recommendation was based on the finding of fewer lacerations in a group of women with no prior cesarean operations. Although it is almost inconceivable that an abdominal operation could predispose the perineum to trauma in a subsequent labor, it may be hypothesized that among women who undergo an initial cesarean section there exists a subgroup of women who are in some way predisposed to later perineal trauma. However, I believe there is a much more straightforward explanation for this study's findings. The 224 patients in the trial of labor group were studied by obtaining their inpatient records and meticulously searching for complications. In contrast, the 6957 patients in the control group were studied by scanning for comments in labor and delivery logbooks. This introduces substantial bias into the study. It is almost certain that actual review of the thousands of control patient' charts would have revealed large numbers of lacerations that were not recorded in the labor logbooks.

The authors also concluded: "Estimates of fetal weight at term should be a part of the decision-making process before vaginal birth after cesarean section is attempted." However, several recent studies have cautioned that current technology cannot accurately identify macrosomic infants before birth.[1] This is true even when the most sophisticated ultrasound techniques and computerized analysis are available.[2] But what if fetal macrosomia could be predicted accurately? The study's finding that infants weighing <3720 gm are more likely to be delivered vaginally than those weighing >3720 gm would still be clinically meaningless. Large babies are more likely to be delivered by cesarean section than small ones. It would have been surprising if this did not apply for the prior cesarean group. In light of the admittedly strict criteria used to diagnose arrest of dilatation, it is remarkable that 47% of the women with infants >3720 gm were able to avoid repeat cesarean operations. In any case the fetal weight recommendation was based on the observation of only 73 cases with fetal weight >3720 gm. A review of our data base reveals 1860 such cases, and 1238 (67%) of these women had successful vaginal births. We recently reported the outcomes of 301 trials of labor with infant birth weights >4000 gm.[3] The majority of these women were delivered vaginally.

Two perinatal deaths occurred in the study by Yetman and Nolan. It should be emphasized that neither case was related to a previous uterine scar. These cases may emphasize the risks of postterm pregnancy, but they do not pertain to vaginal birth after cesarean section. Although the authors found it "sobering" to note that these cases might have been prevented by elective cesarean section at term, the same statement could be made about every postterm fetal death in America.

Finally, it was perplexing that the authors considered a mandatory trial of labor (in the absence of medical contraindications) to be a "quick-fix" measure. If they meant to imply that current trial of labor recommendations were formulated in haste, I would like to remind them that National Institutes of Health and American College of Obstetricians and Gynecologists guidelines were based on the reassuring results of more than 40 studies published over the past 50 years.[4] It is clear that widespread acceptance of vaginal birth after cesarean section could quickly eliminate the need for a large portion of the 1 million cesarean operations performed in this country every year.

Reply

To the Editors: My colleagues and I appreciate the comments by Dr. Flamm regarding our report and are pleased to continue a discussion of so timely an issue as the attempt at vaginal birth after cesarean section and all its ramifications. Dr. Flamm raises three issues that I will attempt to answer in turn.

First, he implies that any difference in the rates of perineal trauma between the study group and the control population are the result of a type of selection bias whereby the study population's complications were "meticulously" searched out while the controls were studied by "scanning" the labor and delivery logbooks. Obviously, to have meticulously studied all 8900 patient records would have been ideal, but this is beyond our capabilities. We are assured that this possible bias is more suspected than real because of the following observation. In none of the 137 successful vaginal births after cesarean section was there any difference between the logbook entries and the representation of perineal trauma found on record review. As in most residency training programs, the rate of significant perineal trauma is tracked and reported in monthly morbidity statistics at our institution. Because we practice at a military hospital and are thus indemnified from personal liability, there is no incentive for underreporting of perineal trauma in the logbooks.

With regard to estimates of fetal weight and their use in deciding to attempt a vaginal birth after cesarean section, again we must state that the fetal weight estimates must not be used in isolation of all other clinical factors that constitute appropriate obstetric care. We do believe that the use of ultrasonographic estimates of fetal weight can add information to the entire clinical "picture" that may be of importance to a particular woman who is trying to make an informed decision about whether to attempt a vaginal birth after cesarean section or undergo a repeat cesarean operation.

Finally, Dr. Flamm seems to misunderstand us with regard to the "quick-fix" measure referred to in our introductory paragraph. Let me state clearly that we have no problem with current recommendations for attempts at vaginal delivery for these women who *desire* such an attempt. There is a vast difference between a recommendation and a mandated solution. In the latter, the patient loses all control over the decision-making process and is left at the mercy of other forces. Unfortunately, the impetus for *mandating* vaginal birth after cesarean section attempts comes not from the medical community but from the insurance industry, motivated by economic interests. We are sure that Dr. Flamm would object to an outside interest that removed any of his patient's rights to make an informed, autonomous decision. It was this mandating of patient care that we were referring to as a "quick-fix" measure. We agree that acceptance of the vaginal birth after cesarean section would inevitably lead to a lower cesarean section rate. However, the persons who need to "accept" this route of birth are those women who have had a prior cesarean section, not their insurance companies, health maintenance organizations, or governmental agencies. If a competent woman is given all the data regarding a proposed procedure and is counseled nondirectively regarding options of near-equal risk, then she must retain the right to make whatever choice seems best for her. We can provide our patients no greater service than this.

Thomas J. Yetman, MD

Maternal serum α-fetoprotein in pregnancy

To the Editors: We do not believe that the data provided by Milunsky et al. (Milunsky A, Jick SS, Bruell CL, et al. Predictive values, relative risks, and overall benefits of high and low maternal serum alpha fetoprotein screening in singleton pregnancies: New epidemiologic data. Am J Obstet Gynecol 1989;161:291-7) support their conclusion that maternal serum α-fetoprotein is "an important adjunctive tool for the identification of high-risk pregnancy and adverse neonatal outcome" when used as a general screen. Because maternal serum α-fetoprotein is of value in screening for specific outcomes of pregnancy, such as fetal neural tube defects and Down syndrome, it does not necessarily follow that maternal serum α-fetoprotein is of value as a screening tool for all adverse outcomes. Milunsky et al. have calculated the sensitivity, specificity, predictive value, and relative risk of an abnormal maternal serum α-fetoprotein value for various specific pregnancy outcomes but not as a general undirected screen. Such a calculation,[1, 2] on the basis of data provided in their Table I is presented in Table I.

The prevalence of the specified adverse outcomes in the authors' study population is 13.4%. When the maternal serum α-fetoprotein value is used as a general screen for any of the possible adverse outcomes, the sensitivity is 11.8% and the specificity 93.3%. The predictive value that abnormality is or will be present is 21.6% when the test result is abnormal (high or low) and 12.8% when the test result is normal. The overall relative risk of the specified abnormalities given an abnormal maternal serum α-fetoprotein value is 1.69 (95% confidence interval, 1.48 to 1.92).

If we remove from the calculation all those categories of adverse outcome listed by Milunsky et al. for which no significant relationship between either high or low maternal serum α-fetoprotein and adverse outcome is shown (stillbirth, polyhydramnios, maternal diabetes, maternal hypothyroidism and hyperthyroidism, and maternal illness), prevalence is reduced to 9.0%, sensitivity is increased to 14.3%, and relative risk is increased to 2.10 (1.80 to 2.45). However, if we further remove from the calculation fetal neural tube defects and chromosome abnormalities that are generally accepted as valid indications for maternal serum α-fetoprotein screening, the prevalence is reduced to 8.7%, sensitivity is reduced to 12.5%, and relative risk is reduced to 1.87 (1.56 to 2.19).

Table I. Recalculated data of Milunsky et al.

	All outcomes	*Outcomes with RR > 1.0*	*Outcomes with RR > 1.0 (excluding neural tube defects and chromosomes)*
RR and 95% CI	1.69 (1.48-1.92)	2.10 (1.80-2.45)	1.85 (1.56-2.19)
Prevalence (%)	13.4	9.0	8.7
Sensitivity (%)	11.8	14.3	12.5
Specificity (%)	93.3	93.3	93.3
PTL+ (%)	21.6	17.6	15.3
PTL− (%)	12.8	8.4	8.2

RR, Relative risk; *CI*, confidence interval; *PTL+*, positive posttest likelihood; *PTL−*, negative posttest likelihood.

We do not question the value of maternal serum α-fetoprotein screening in the prenatal diagnosis of fetal neural tube defects and chromosome abnormalities. However, we question its value as a general screening tool for prediction of "high-risk" pregnancy. With the figures calculated for those outcomes associated with increased relative risk, maternal serum α-fetoprotein screening detects only one in seven and misses six in seven of the pregnancies that progress to the adverse outcomes listed in Table I of Milunsky et al. Further, an abnormal test outcome results in false labeling of a pregnancy as "high risk" 8 times in 10.

We do not believe these figures justify the use of maternal serum α-fetoprotein screening as a general test for "high-risk" pregnancy. Use of maternal serum α-fetoprotein as a general screen for "high-risk" pregnancy could be evaluated more thoroughly in a double-blinded prospective trial of management comparing a "high-risk" protocol versus "routine" obstetric care in women with abnormal maternal serum α-fetoprotein levels.

Reply

To the Editors: Gilchrist et al. are correct. Maternal serum α-fetoprotein screening cannot yet be used "as a general screen" for identifying high-risk pregnancy. However, elevated maternal serum α-fetoprotein values, in the absence of a detectable fetal defect, indicate a breach in the integrity of the maternal-fetal interface. Therefore our observations of increased relative risks for specific complications in a very carefully followed-up cohort of 13,846 women should alert the obstetrician to exercise anticipatory surveillance. It would seem injudicious to ignore a relative risk of 2 to 4.7 for oligohydramnios, abruptio placentae, preeclamptic toxemia, premature ruptured membranes, low birth weight, neonatal death, and other major congenital defects. In association with unexplained maternal serum α-fetoprotein elevations, others have noted a significant increased incidence of low birth weight,[1] fetal loss, neonatal death, and various nonleaking congenital defects.[2] The majority of pregnancies with elevated maternal serum α-fetoprotein levels conclude with a normal child. Nevertheless, such observations may serve as an early warning and hence maternal serum α-fetoprotein levels could also be used as an "important adjunctive tool."

Treatment of cervical pregnancy with methotrexate

To the Editors: I read with interest the report by Palti et al. (Palti Z, Rosenn B, Goshen R, Ben-Chitrit A, Yagel S. Successful treatment of a viable cervical pregnancy with methotrexate. Am J Obstet Gynecol 1989; 161:1147-8). Although I appreciate the importance of this therapeutic modality, I would stress that a prerequisite is, of course, correct ultrasonographic diagnosis before severe hemorrhage occurs. Cervical suture, as described by Bernstein et al.[1] and referenced by the authors, still remains in the obstetrician's armamentarium as a potential conservative surgical aid to control massive hemorrhage in an acute situation usually undiagnosed before presentation (as originally described).

With reference to the figure in the article, although Fig. 1, *A*, clearly represents a transabdominal ultrasonogram, it is not clear whether Fig. 1, *B*, was obtained transabdominally or by endovaginal ultrasonography.

Coronal section (as defined in *Gray's Anatomy*[2] as vertical planes at right angles to the median-sagittal plane) of the pelvic organs is only obtainable by the endovaginal route. In fact a recent publication has suggested that the term *trans*-pelvic scan is more appropriate for the plane imaged when the sound beam is directed from side to side in the pelvis during endovaginal sonography.[3] Therefore, if Fig. 1, *B*, was performed transabdominally (as it appears to have been), it should be correctly termed a *transverse* section rather than a *coronal* section.

Inasmuch as methotrexate has rarely been applied to viable pregnancies, it would have been interesting to note the histopathologic findings of this case, which presumably reflect the effect of methotrexate on this viable pregnancy.

David M. Sherer, MD

3. Dodson MG, Deter RL. Definition of anatomical planes for use in transvaginal sonography. JCU 1990;18:239-42.

Reply

To the Editors: We appreciate the letter by Dr. Sherer concerning our article. However, we disagree with him that coronal section of the uterus and cervix is obtainable only by the endovaginal route. With some experience, transabdominal coronal section of the uterus and cervix can be achieved by pressing the woman's lower abdomen by the sector probe, as clearly demonstrated in Fig. 1, *B*.

With regard to his second question, histopathologic examination revealed nonspecific missed abortion pathologic changes.

Caution in use of new test for ectopic pregnancy

To the Editors: The article by Lindblom et al. (Lindblom B, Hahlin M, Sjöblom P. Serial human chorionic gonadotropin determinations by fluoroimmunoassay for differentiation between intrauterine and ectopic gestation. Am J Obstet Gynecol 1989;161:397-400) contributes to the difficult problem of diagnosing ectopic pregnancy when serial human chorionic gonadotropin titers are rising. However, several issues relevant to interpretation of a new diagnostic test are not addressed in the article. I believe that understanding more about the value of tests under different testing conditions might influence significantly readers' use of these three new tests.

Forty-six percent of the study population to whom the test was applied (N = 41) had ectopic pregnancies. This proportion is much higher than that seen in the typical outpatient American population followed to rule out ectopic pregnancy. If the proportion of patients with true ectopics was only 20%, for example, then the positive predictive value of the three tests (absolute slope, relative slope, and human chorionic gonadotropin score) would be 82%, 82%, and 83.7%, respectively. This is a clinically relevant decrease from the values for a 46% ectopic prevalence of 94.1%, 94.1%, and 94.7%, respectively. (Note that the values in Table II are actually sensitivity for the test applied to diagnose intrauterine pregnancy and ectopic, *not* predictive value, as stated).

Second, in contemporary American medical practice it is not possible to hospitalize for evaluation so many patients who ultimately prove not to have ectopic pregnancies (indeed almost 30% were not even pregnant). Thus the American physician will not always have the luxury of waiting 1 to 6 days with a patient in the hospital to gather information necessary to apply this test.

Finally, it seems unusual that five of the patients with ectopic pregnancies but none of the patients with intrauterine pregnancies were resampled on day + 1 and only two (versus 11 patients with intrauterine pregnancies) were resampled after day + 3. Could this represent some bias in the application of the test?

Susan T. Haas, MD

Department of Obstetrics and Gynecology, Brigham and Women's Hospital, 333 Longwood Ave., Boston, MA 02115

Reply

To the Editors: We appreciate the considerations in Dr. Haas' letter that highlight important principles of test evaluation. Her comments concerns three items: prevalence of the disease, hospitalization time, and sample interval.

Concerning the prevalence of ectopic pregnancy in the study population (46%), we agree that this figure may seem high. However, it was the real proportion of ectopic pregnancy in the group to which the human chorionic gonadotropin score was applied. We believe that the following factors account for the high prevalence: (1) liberal use of endovaginal ultrasound, which accurately (and indeed rapidly and easily) recognized viable intrauterine pregnancies in a large proportion of early pregnant women; (b) the widespread knowledge in our community of risk determinants[1,2] implies that few ectopic pregnancies were "lost" for serial human chorionic gonadotropin determination because of late presentation and emergency surgery; (3) exclusion of cases with decreasing human chorionic gonadotropin levels, which are not compatible with viable pregnancy.

From the results presented, it is easy to extract the sensitivity, specificity, and positive/negative predictive values. We used the positive predictive value to compare the performance of the human chorionic gonadotropin score with the other methods applied (abso-

lute slope, relative slope). The positive predictive value (P), which is valuable for the busy clinician, is the conditional probability of "disease" (D+), that is, ectopic pregnancy, given a "positive" test, i.e., abnormal human chorionic gonadotropin score (T+). Thus P D+/T+ = 18/19 = 0.947 = 94.7%. The sensitivity clearly deals with the opposite proportion, the conditional probability of a positive test, given that the woman has the disease (P T+/D+). In this particular case, these fractions happen to be identical because there were one false-positive and one false-negative test result. Thus P T+/D+ = 18/19 = 0.947 = 94.7%. For the same reason, the specificity (P T−/D−) in this particular sample is identical to the negative predictive value (P D−/T−) = 21/22, where D− is "disease free" (intrauterine pregnancy) and T− is negative test result (normal human chorionic gonadotropin score).

With regard to the hospitalization time, we obviously misused the term "admitted." The majority of our patients were not hospitalized but were managed as outpatients.

Theoretically a difference in sampling interval between the two groups of cases could represent a bias. However, our calculations suggest that the small difference in sample interval does not significantly change the performance of the human chorionic gonadotropin score in this patient group. We currently use a sample interval of 1 to 2 days, which was also recommended in our article.

Perception of teratogenic risk by pregnant women exposed to diagnostic radiation during pregnancy

To the Editors: We greatly enjoyed the article by Koren et al. (Koren G, Bologa M, Long D, Feldman Y, Shear NH. Perception of teratogenic risk by pregnant women exposed to drugs and chemicals during the first trimester. Am J Obstet Gynecol 1989;160:1190-4). The authors state in their conclusions that the perception of teratogenic risk is one of the factors that may lead pregnant women to consider pregnancy termination and that this perception is often determined or supported by wrong information given by health personnel.

We agree with the conclusions of Koren et al. inasmuch as we are faced with the same problem in our experience in reproductive counseling (Telefono Rosso in Rome). In particular, we noted that exposure to diagnostic radiation is an important risk factor as perceived by pregnant women.

Between June 1, 1988, and October 30, 1989, a total of 1097 requests for reproductive counseling were received. A total of 82 requests (7.5%) referred to exposure to diagnostic radiation. The time of exposure varied between the preconceptional period and 9 weeks' gestation. The total amount of radiation varied from 1 mrad to approximately 1300 mrad, a range that is not associated with a measurable risk for the fetus.[1,2]

In 50 cases (61%) the women had already consulted a physician. The physician gave a high-risk estimate in 37 cases (74%), giving a generic high-risk estimate in 20 cases, recommending prenatal diagnosis in 5 cases, and advising the women to consider pregnancy termination in 12 cases. It appears from our experience that a misperception of teratogenic risk from diagnostic radiation effectively exists, and that it may cause a state of anxiety in these women to lead them to consider pregnancy termination.

This misperception is often related to imprecise knowledge of the problem on the part of the physician. More specifically, we identified two major problems. The first relates to the difficulty of conveying the difference between the prospective preexposure approach to diagnostic radiation and the risk assessment after the exposure. Second is the imprecise and incomplete information on reproductive risk factors available in some standard textbooks and reviews.

Reply

To the Editors: We thank Dr. Mastroiacovo and his colleagues for their important input on the misperception of teratogenic risk in cases of gestational exposure to radiation. With the use of the analogue scales reported in our original article we have recently completed analysis of risk perception in women undergoing diagnostic radiation.

Our results agree with the experience from Rome; the assigned perception of teratogenic risk was almost double that of other women exposed to nonteratogens (Bentur Y, Horlatsh N, Koren G. Unpublished observations).

This is certainly an important area in which obstetricians, general physicians, and teratogen consultation services could prevent a large number of unnecessary pregnancy terminations.

Conservative treatment of ovarian pregnancy by local prostaglandin $F_{2\alpha}$ injection

To the Editors: Conventional surgical treatment for ovarian pregnancy is associated with subsequent infertility. Egarter et al.[1] reported on the management of tubal pregnancy by intratubal injection of prostaglandin (PG) $F_{2\alpha}$ and additional synthetic PGE_2 analog. However, we are not aware of a report on the conservative approach of ovarian pregnancy by local injection of $PGF_{2\alpha}$. This is the first successful case of ovarian pregnancy treated with $PGF_{2\alpha}$ of which we are aware.

The patient was a 30-year-old infertile nulliparous woman who was first seen with spotting and left abdominal pain 6 weeks after her last menstrual period. Pregnancy test results were positive. Her uterus was empty, and a small ringlike structure near the left tubal region was noted by transvaginal ultrasonographic examination.

After obtaining informed consent, routine diagnostic laparoscopy was performed with confirmation of the diagnosis. After the ruptured left ovarian pregnancy was confirmed laparoscopically, laparotomy was performed to close the affected ovary. A part of the affected ovary was resected for the pathologic diagnosis and then the rupture was closed. Thereafter, 0.5 mg of prostaglandin $F_{2\alpha}$ was gently injected into the affected ovary. Then 10 mg of estrogen was instilled into the corpus luteum of pregnancy without complications. An additional dose of 3 × 0.5 mg PGE_2 (dinoprostone) was administered orally for 14 postoperative days. Serum β-human chorionic gonadotropin (hCG) and pregnancy-specific β_1-glycoprotein reached nonpregnant levels within 1 week of $PGF_{2\alpha}$ treatment. Fig. 1 shows the serum β-hCG and β_1-glycoprotein results. Lindblom et al.[2, 3] have shown that $PGF_{2\alpha}$ invariably causes powerful contractions as well as an antigonadotropic (i.e., luteolytic) action. Karsch et al.[4] have shown that estrogens can induce functional luteolysis in the rhesus monkey by acting directly within the ovary that contains the corpus luteum.

These results suggest that $PGF_{2\alpha}$ may be useful for pharmacologic treatment of selected cases of ovarian pregnancy.

Early hypothyroidism in patients with menorrhagia

To the Editors: We read with interest the article by Wilansky and Greisman (Wilansky DL, Greisman B. Early hypothyroidism in patients with menorrhagia. Am J Obstet Gynecol 1989;160:673-7) in which they showed that of 67 women presenting with menorrhagia, 15 had evidence of primary hypothyroidism. The menorrhagia disappeared on treatment with thyroxine, suggesting a cause-and-effect relationship between hypothyroidism and menorrhagia. A potential intermediary in this relationship might be the factor VIII molecule.

We recently reported a case of a 17-year-old woman who came for treatment for severe anemia caused by menorrhagia and hypothyroidism.[1] Coagulation studies showed a pattern of von Willebrand's disease (type I). There was no family history of von Willebrand's disease. On correction of thyroid status with oral L-thyroxine, coagulation defects returned to normal and menorrhagia ceased.

The association of acquired von Willebrand's disease and hypothyroidism has been recognized recently.[2-4] In some cases, menorrhagia has been reported at the time of presentation and has resolved with thyroxine therapy.

The results of coagulation studies were not reported by Wilansky and Greisman; it would be interesting to know if consideration was given to the possibility of an underlying bleeding disorder in their patients.

We believe there is a true association between hypothyroidism and acquired von Willebrand's disease, and it is the latter hemostatic abnormality that results in menorrhagia. Wilansky and Greisman are to be congratulated in alerting gynecologists to this "medical cause" of menorrhagia that can easily and effectively be treated. We would ask that in addition to thyroid function tests, coagulation studies be performed in women presenting with menorrhagia and hypothyroidism.

Reply

To the Editors: The observation by Blesing and Hambley indicating a von Willebrand–like syndrome in certain hypothyroid patients was of great interest. We have not done detailed coagulation studies in our patients, and the frequency and significance of their preliminary observations will be determined in further studies.

The precise physiopathologic mechanism of menorrhagia in hypothyroidism has not to date been clearly established. The endocrine disturbance in pituitary-ovarian interrelationships suffices to account for menorrhagia. The observations of Blesing and Hambley point to an additional potential predisposing mechanism.

Should amniocenteses always accompany unexplained high maternal serum α-fetoprotein levels? Who decides: Public agency, patient, or private physician?

To the Editors: I agree with Hogge et al. (Hogge WA, Thiagarajah S, Ferguson JE, Schnatterly PT, Harbert GM. The role of ultrasonography and amniocentesis in the evaluation of pregnancies at risk for neural tube defects. Am J Obstet Gynecol 1989;161:520-4) that, when ultrasonography is done as a "targeted examination" within the framework of a "comprehensive" prenatal diagnosis center where the physician is a "consultant ultrasonologist," it is possible, in selected cases, to accurately omit genetic amniocentesis testing for evaluation of a high level of maternal serum α-fetoprotein.

However, there are several other issues that must be discussed with the patient: Abnormal sex chromosomes have been detected on chromosome analysis of the amniotic fluid in a larger prospective study (the State of California Department of Health Services maternal serum α-fetoprotein program). These patients also appear to be in an increased risk category for high-risk pregnancy problems in the third trimester, and although knowledge of the abnormal chromosomes is not essential for third-trimester high-risk pregnancy management, that perspective is not alluded to in this letter or in the discussion.

The policy of the State of California Department of Health Services maternal serum α-fetoprotein program has been challenged, but the most recent "directive" is that it will continue to be the recommended standard of care that all patients have offered to them genetic amniocentesis for evaluation of a high maternal serum α-fetoprotein level, even in the presence of a normal fetal ultrasonogram.

I would be interested to know of the pregnancy outcome regarding possible high-risk pregnancy factors in the patients from this study in whom the pregnancies continued with normal fetal sonograms.

John D. Stephens, MD
California Prenatal Diagnosis Institute, 1390 S. Winchester Blvd., San Jose, CA 95128

Editors' note: Dr. Stephens is not authorized to speak for the State of California Department of Health Services.

REFERENCE

Reply

To the Editors: We appreciate Dr. Stephens' interest in our article on the evaluation of pregnancies at risk for neural tube defects. First, it is necessary that we respond to his statement that it is possible to accurately omit genetic amniocentesis testing for evaluation of high maternal serum α-fetoprotein in selected cases. We strongly believe that each center must evaluate its own experience with ultrasonography and amniocentesis in the detection of neural tube defects, and present this information to the patient in a nondirective fashion. Similarly, the patient should be informed that, at the present time, the accepted practice for evaluation includes amniocentesis. Until large prospective studies are completed in a number of institutions, no change in our present diagnostic approaches should be made.

Second, we are aware of anecdotal reports of chromosome aneuploidy found at the time of amniocentesis for the evaluation of an elevated maternal serum α-fetoprotein. However, the incidence of aneuploidy in the absence of ultrasonographic abnormalities of the fetus is not known. In our series no cases of aneuploidy were found in either the group that had amniocentesis, or those who chose ultrasonography only. The other large studies similar to ours report a similar experience.[1, 2] We would be interested in the California experience with "abnormal sex chromosomes." Is the incidence higher than the general population (newborn) incidence, and is it high enough to justify the risk of amniocentesis?

Third, although the analysis of obstetric complications has not been completed in our series, there are no trends that differ significantly from those reported by Milunsky et al.[3] and Robinson et al.[4] The methods for monitoring these clearly high-risk patients have not been established, but certainly most of the published obstetric complications associated with elevated maternal serum α-fetoprotein are not the result of chromosome aneuploidy. Unless the incidence of aneuploidy can be shown to be significantly increased in this group of patients with adverse pregnancy outcome, there would be no justification to add the detection of aneuploidy to the indications for amniocentesis in this subgroup of patients. We look forward to the prospective data possible through the California maternal serum α-fetoprotein screening program to help answer these questions.

Flow cytometric quantitation of tumor-associated antigens in solid tumors

To the Editors: We read with great interest the article by Nozawa et al. on the application of the monoclonal antibody MSN-1[Nozawa S, Sakyori M, Kunihiko O, et al. A monoclonal antibody (MSN-1) against a newly established uterine endometrial cancer cell line (SNG-11) and its application to immunohistochemistry and flow cytometry. Am J Obstet Gynecol 1989;161:1079-86]. In their article the authors described a single parameter flow cytometric assay for the quantitation of MSN-1 in normal endometrium and endometrial carcinoma. Although we agree that immunofluorescence analysis using flow cytometry in conjunction with monoclonal antibodies is very useful for quantification of tumor-associated antigens in heterogeneous cell systems such as solid tumors, in our opinion future investigators should be encouraged to use multiparameter flow cytometry for this type of measurement.

All the mechanical and/or enzymatic tissue dissociation methods currently available inevitably produce a certain amount of cellular debris and dead cells. In our experience this contributes to a highly variable nonspecific fluorescent background that is difficult to allow for using single-parameter flow cytometric techniques since there can be problems in identifying the viable cells by scatter analysis alone. Conversely, simultaneous flow cytometric analysis of cell suspensions for deoxyribonucleic acid, cell volume, and tumor-associated antigens allows much better correction for fluorescent background and makes the assay much more sensitive and reproducible.[1] By plotting deoxyribonucleic acid against the 90-degree scatter pulse width, the morphologically intact cells can be separated from cell debris and clumps, and most of the small volume inflammatory cells and some of the stroma cells can be gated out. Tumor-associated antigens expression can then be calculated in the gated regions only, which contain intact tumor cells and some stromal cells. This is one of the main advantages of flow cytometry over more conven-

tional methods such as radioimmunoassay and immunoblot techniques.[1-3]

Reply

To the Editors: We agree with the correspondents' multiparameter approach to the flow cytometric measurement of tumor-associated antigens. However, two technical matters arose in the case of the endometrial cancers we studied. First, in preliminary measurements of deoxyribonucleic acid in these cancer cells, we found that the deoxyribonucleic acid in two thirds of the well-differentiated endometrial cancers examined, of which cancers are histologically the most common type, was diploid and that in one third was aneuploid (nearly diploid). Furthermore, the deoxyribonucleic acid indices of the aneuploidy cases were below 1.2, suggesting that the strict gating of the cancer cells is very difficult.

Second, we found that the reactivity of the glycolipid antigen on the cell surface with MSN-1 antibody often changes following the fixation procedure that is a necessary step for deoxyribonucleic acid staining. Therefore in our study we performed immunostaining on nonfixed cells; this, however, makes the differential diagnosis between cell debris without nuclei and cells with nuclei difficult because the deoxyribonucleic acid of the nonfixed cells is barely stained by propidium iodide.

For these reasons it is not easy to establish a method for simultaneous measurement of MSN-1 antigen and deoxyribonucleic acid, but the combination assay of deoxyribonucleic acid and tumor-associated antigen currently seems to be the best way. We would like to accumulate basic data to develop a new supplemental method for the diagnosis of endometrial cancers, which are increasing in Japan and are sometimes difficult to diagnose on endometrial cytologic specimens.

Effects of ritodrine tocolysis on cardiac isozymes and electrocardiography

To the Editors: We read the article by Drs. Hadi and Albazzaz (Hadi HA, Albazzaz SJ. Cardiac isoenzymes and electrocardiographic changes during ritodrine tocolysis. Am J Obstet Gynecol 1989;161:318-21), a study of 40 patients in preterm labor, with great interest. We are gratified to see confirmation of our publication of 112 patients similarly treated.[1]

In our study, serial electrocardiography and electrolyte measurements were performed before intravenous ritodrine therapy and at 6 and 24 hours of treatment. Ninety-six percent of our patients developed sinus tachycardia. ST segment depression (>1 mm) was seen in 70%, T-wave flattening or inversion in 55%, and prolongation of the QT interval in 35%. We saw no correlation between chest pain and electrocardiogram (ECG) changes. There was no direct correlation between potassium concentration and ECG changes in our study, although all treated patients showed some degree of hypokalemia relative to their pretherapy levels. Drs. Hadi and Albazzaz looked at maternal blood pressures, pulse rate, and serum electrolyte levels, but there was no attempt to correlate electrolyte changes, blood pressure changes, or pulse changes with the corresponding electrocardiographic changes.

In the current study it is unclear how frequently ECGs were ordered and whether the results of the study reflect ECGs performed at 6 hours or at 12 hours after the initiation of intravenous ritodrine therapy. Did the authors consider the ECG changes seen at the two individual time intervals? As our article clearly noted, the majority (89%) of ECG and electrolyte changes reverted to near baseline levels at 24 hours although intravenous ritodrine tocolysis was continued. These findings refute the authors' postulation that continued therapy in these patients will lead to myocyte damage. It should be noted that no change in isozyme concentration was noted during tocolysis in their study. Similarly, three previous studies have evaluated correlations of serum enzymes and/or serum creatine kinase, MB fractions, or serum myoglobin levels with ECG changes but no deviation of isozymes was seen, again arguing strongly against myocyte damage.[2-4]

We applaud the authors' conclusion that no evidence of direct cardiotoxic effects of ritodrine could be demonstrated but find their final recommendation (discontinuation of ritodrine in the face of symptoms of ischemia or ECG changes) unsettling. Our conclusion was and still is exactly the opposite. We found no correlation between chest pain and ECG changes and, indeed, like the authors, suspect that the ECG changes as seen are related to either the hypokalemia seen with β-adrenergic receptor agonists or the induced tachycardia that may cause ECG changes like those seen in athletes under similar tachycardiac conditions. In twin gestations the baseline cardiovascular changes (increased cardiac output and sinus tachycardia) are accentuated over those of singleton gestations, and the additional cardiovascular changes caused by β-

adrenergic receptor agonists would likely be more marked, as seen by the authors. Development of a sinus tachycardia is often accompanied by a relative decrease in blood flow to the subendocardium, which may cause subtle changes in maternal electrocardiograms even in the absence of functional ischemia and isoenzyme changes. This is considered a physiologic adaptation and has not been associated with proven pathologic conditions.[2] Because there is no sign of myocyte damage (normal isozymes and creatine kinase MB fractions) in treated patients, it seems unlikely that myocardial damage is occurring.[2] Our previous findings would also indicate that these ECG changes are very frequent in patients undergoing tocolysis with β-adrenergic receptor agonists and that, as previously noted, they resolve spontaneously over time even in the presence of continued intravenous tocolysis.

Finally, further insight regarding myocardial ischemia will likely require the development of an animal model to assess intracardiac ECGs during tocolysis with concomitant evaluation of cellular cardiac isozymes, gases, and lactic acid levels. In the absence of these data, there is no clinical evidence that pathologic changes in cardiac function are taking place during ritodrine tocolysis, and we suggest that ECG changes are not an indication for discontinuation of β-adrenergic tocolytic therapy.

Reply

To the Editors: We would like to thank Drs. Hendricks and Katz for their interest in our article and for sharing some aspects of their work with us regarding this complex subject.

Our study was designed to use a combination of creatine kinase (CPK-MB), lactate dehydrogenase (LDH) subunits, LDH_1/LDH_2 ratio, and electrocardiography to investigate the possible myocardial ischemic effects of ritodrine tocolysis. It has been previously reported that the use of electrocardiography alone for diagnosis of myocardial infarct is somewhat insensitive; therefore study of cardiac enzymes, as well as ratio of LDH_1 to LDH_2, has become a significant test in these situations.[1] It has also been noted that sensitivity of electrocardiography for detection of myocardial ischemia during exercise testing is relatively low.[2]

During ritodrine tocolysis, changes such as hypokalemia (a shift of potassium from extracellular to intracellular space without total body potassium loss), low diastolic blood pressure, and maternal tachycardia are known side effects of the drug, which has been studied extensively in humans, as well as in animal models.[3, 4] Therefore we did not correlate such changes with electrocardiogram (ECG) results in our study. The fact that Drs. Hendricks and Katz did not find direct correlation between serum potassium concentration and ECG changes is not surprising.

Our study consisted of three periods: before ritodrine infusion, at 6 and 12 hours during infusion, and within 24 hours of oral drug therapy. Changes in ECGs in our study reflected those observed during ritodrine infusion periods when hemodynamic alterations were at maximum.

We found the authors' statement that the majority (89%) of ECG changes in their series reverted to near baseline at 24 hours, even though intravenous ritodrine tocolysis was continued, inconsistent with their previous report. Katz et al.[5] reported cardiovascular complications in 116 patients treated with terbutaline (a β-adrenergic receptor agonist similar to ritodrine) for preterm labor. In eight patients pulmonary edema developed, the majority with ECG changes indicative of myocardial ischemia that did not disappear for 24 hours after discontinuation of tocolytic treatment. Furthermore, the same observation was noted in one of their patients who did not have pulmonary edema. Because maternal tachycardia is a well-known effect of ritodrine therapy, the ECG changes in the authors' recent study may have been the reflection of a faster heart rate and not ischemia or, alternatively, ischemia that resolved as the heart rate decreased. This possibility was not clarified, specially when no other cardiac evaluations including enzyme studies were carried out.

Drs. Hendricks and Katz stated that ECG changes during ritodrine tocolysis are considered similar to the physiologic adaptation seen in athletes under tachycardiac conditions.They also suggest that, in the face of symptoms of ischemia or ECG changes, ritodrine tocolysis should not be discontinued. We disagree with their contentions and consider such recommendations dangerous for practitioners in the absence of adequate data. Mechanisms of cardiovascular and pulmonary complications of ritodrine are unclear at the present time. Hemodynamic effects of ritodrine should not be compared to a physiologic adaptation seen during exercise because of the following:

1. Exercise has a limited period of time (i.e., minutes to a few hours), while inotropic and chronotropic effects of ritodrine generate hemodynamic changes for 24 hours of infusion. No individual could tolerate such changes for a prolonged period of exercise. Thus it is possible that prolonged cardiac effects of ritodrine disturb the subendocardial oxygen supply/demand ratio and

precipitate myocardial ischemia and, if not treated properly, may proceed to myocyte damage.
2. Pharmacologic effects of ritodrine are different from changes considered as physiologic adaptations of exercise. These changes consist of metabolic effects, including those of glucose, sodium, potassium, renin, angiotensin, and arginine vasopressin, water homeostasis, and renal and cardiopulmonary effects. These changes individually or cumulatively predispose the patient to cardiopulmonary complications that are quite different from tachycardia seen during exercise.
3. Additional increases in blood volume and cardiac output in pregnant women, especially in twin gestations will be added risk factors to cardiopulmonary complications. The authors' most recent study, which already included two life-threatening cases of angina with normal ECGs and in one of which pulmonary edema developed, supports the notion that an ECG alone cannot be used as the sole marker of therapy in these cases.

In view of the life-threatening cardiovascular and pulmonary nature of ritodrine complications and the lack of adequate data in this regard, we believe, in the presence of ECG changes and/or chest pain, that ritodrine tocolysis should be discontinued. Furthermore, patients should be given oxygen and additional cardiac assessment and cardiology consultation should be carried out.

Finally, we agree with Drs. Henricks and Katz that further insight regarding this complex issue requires development of an animal model and more detailed cardiac studies before we suggest that ECG changes are not an indication for discontinuation of ritodrine therapy.

Inhibitory cofactor of antiphospholipid antibody in normal pregnancy sera

To the Editors: Lockwood et al. recently reported a study to establish the causative nature of antiphospholipid antibody on adverse pregnancy outcomes (Lockwood CJ, Romero R, Feiberg RF, Clyne LP, Coster B, Hobbins JC. The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population. AM J OBSTET GYNECOL 1989; 161:369-73). We would like to complement their observations with our recent finding of high levels of antiphospholipid antibody, commonly present in sera from normal healthy individuals.[1] These antiphospholipid antibodies in sera from normal healthy individuals are normally undetectable by a sensitive enzyme-linked immunosorbent assay (ELISA), but their presence is revealed when sera are first preheated at 56° C for 30 minutes before ELISA testing.[2] The antiphospholipid antibodies in normal healthy individuals were mostly IgG and exhibited the classical selective binding, as reported for antiphospholipid antibody in clinical sera, to negatively charged phospholipids including cardiolipin, phosphatidylserine, and phosphatidic acid.[1, 3] This strongly indicates the existence of heat-labile serum inhibitory cofactor(s) of antiphospholipid antibody, with such complexes in normal healthy individuals being undetectable by ELISA. The ELISA detection of such autoantibodies may thus reflect a reduction of antiphospholipid antibody–masking factor(s). In other words, any pathogenicity of antiphospholipid antibody may not necessarily result from a hyperimmune response to cell membrane phospholipids but rather a consequence of a pathophysiologic decrease in the antiphospholipid antibody inhibitor. In this regard, we have similarly found antiphospholipid antibody in 29 of 31 normal pregnancy sera after heat inactivation of the sera. We are progressing with investigations to characterize the antiphospholipid antibody regulatory cofactor and to better understand the immunogenesis of antiphospholipid antibody in nonclinical sera.

Response declined

The local anesthetic dose is an important issue in evaluation of effects of epidural analgesia in nulliparous women

To the Editors: My colleagues and I appreciated the article by Thorp et al. (Thorp JA, Parisi VA, Boylan PC, Johnston DA. The effect of continuous epidural analgesia on cesarean section for dystocia in nulliparous women. AM J OBSTET GYNECOL 1989;161:670-5). We thought the authors did an excellent job in describing the relationship between epidural analgesia during la-

bor and incidence of cesarean section for dystocia, which may stem from such a technique. The results were analyzed, taking into account objective sources of error, and suggested a need for further investigation.

However, there was a point in the study that may need clarification. Thorp and colleagues did not specify the dose of bupivacaine administered. Indeed, the first injection was described as an "initial bolus injection of bupivacaine 0.25%," whereas the following dose was indicated as a "continuous infusion of 6 to 12 ml/hr of 0.125% solution." The mean infusion time was not given. It has been widely discussed that pregnancy increases the effectiveness of local anesthetics.[1] Therefore it has been suggested that the administered dose should be as small as possible to avoid untoward effects such as instrumental delivery and distressing motor blockade.[2] In the aforementioned work it was quite difficult to quantitate either the first or the total dose of bupivacaine. We believe this is a very important issue to address because dystocia could be related to the total amount of local anesthetic received by the patient.

In addition, we would like to reflect on the continuous infusion method used to maintain analgesia. Different epidural analgesia techniques may produce different drug levels and relative effects on the body. In a previous study Griffiths and colleagues[3] demonstrated that epidural analgesia, given by a constant infusion of bupivacaine 0.25% to 0.125%, yields a cumulative dose twice as large as that produced by repeated 0.5% bupivacaine injections. Also, in the first condition bupivacaine plasma levels were close to the toxic threshold, whereas no bupivacaine was found in plasma in the second one. In Thorp et al.'s study there was no comparison of incidence of cesarean section for dystocia between a nulliparous group of women in which a continuous infusion of 0.125% bupivacaine was given, and one receiving small 0.25% bipuvacaine top-up injections under patient request. What if the infusion time were such to allow bupivacaine accumulation? If that were the case, the results may represent an uncontrolled bupivacaine dose-effect.

Finally, the epidural use of other drugs should be explored. Opioids such as fentanyl citrate have been successfully used to relieve pain in the first stage of labor.[4] Although opioids may not be sufficient to provide adequate analgesia in all stages of labor, the synergism between local anesthetics and opioids is suitable for further investigation.[5] It may be possible that such a pharmacologic association reduces both local anesthetic dose and unwanted effects on delivery.

Reply

To the Editors: We appreciate the interest in our research. Puppa and colleagues make several valid criticisms about any retrospective study design (i.e., there are numerous variables that were not controlled). The mean epidural infusion time was not analyzed. We agree that the total dose of bupivacaine may well be an important determinant of labor outcome. Despite the data of Griffiths et al.,[1] there are legitimate concerns about repeated boluses of 0.5% bupivacaine during labor. Continuous infusion technique is generally considered safer than repeated boluses because of the potential for toxic reactions from inadvertent intravascular bolus injection. In addition, the 0.5% bupivacaine solution would have a greater potential to affect the course of labor because it causes a more dense motor blockade than that of the 0.125% or 0.25% solution.

In institutions in which the staff are acutely aware of the potential of epidural analgesia to interfere with labor, the adverse effects may be limited. However, in institutions in which there is a lack of experience or concern, epidural analgesia may have a profound effect on the incidence of instrumental delivery and cesarean section. There is a large variation in epidural technique between institutions. Many factors involved with the epidural technique may influence the course of labor (e.g., fluid bolus, cervical dilatation at which the epidural infusion is placed, concentration of anesthetic agent, volume of anesthetic agent, and management of the epidural infusion in the second stage of labor). Perhaps as important as the epidural technique itself is the variation in the obstetrician's response to dystocia. A recent study[2] showed that with the same anesthetic service, epidural analgesia was associated with a 16-fold greater incidence of cesarean section for dystocia in the private service as compared with the clinic service. In this study,[2] epidural analgesia was associated with an increase in cesarean section for dystocia on the private service but not on the clinic service. The authors[2] speculate that the difference may be attributed to a more aggressive use of oxytocin in the clinic patients compared with the private patients. As Neuhoff et al.[2] point out, if uterine activity is not restored in a timely fashion, "the psychology of prolonged and non-progressive labor dominates management strategies, as the physicians, patients, and families become exhausted and frustrated . . .."

The question of whether epidural analgesia increases the incidence of instrumental vaginal delivery or ce-

sarean section has not been adequately addressed in a randomized prospective study. To address the selection bias issues, the ideal study must randomize patients in early labor to an epidural or a nonepidural group. In view of our article in the JOURNAL and another study[3] that shows a significant association between epidural analgesia and cesarean section for dystocia in nulliparous labors, this definitive study must be done.

Colposcopy in diethylstilbestrol-exposed offspring

To the Editors: I would like to comment on the article by Helmerhorst et al. (Helmerhorst TJM, Wijnen HJA, Kenemans P, et al. Colposcopic findings and intraepithelial neoplasia in diethylstilbestrol-exposed offspring. AM J OBSTET GYNECOL 1989;161:1191-4) in the JOURNAL. The authors stated that, in their opinion, colposcopic evaluation of diethylstilbestrol-exposed offspring requires special expertise and is therefore recommended to be performed only in regional centers by expert colposcopists to prevent unnecessary biopsies. However, they discussed at some length the possible increased risk of intraepithelial neoplasia of the cervix and vagina in diethylstilbestrol-exposed offspring. I do not feel that their conclusions can be drawn from the information presented. I agree that expertise in colposcopy is necessary for anyone using this method to help in the identification of low-grade intraepithelial neoplasms, but I do not think that the technique of colposcopy is so difficult that individuals who practice in areas outside of regional referral centers cannot be trusted to perform the procedure. I would also seriously question these "experts" on their ability to differentiate which diethylstilbestrol-exposed patients with abnormal colposcopic findings require a biopsy and which do not.

Gregory L. Gimbel, MD
Department of Obstetrics and Gynecology, Parkview Memorial Hospital, Brunswick, ME 04011

Reply

To the Editors: We agree with Dr. Gimbel that colposcopy is currently practiced in most gynecology departments. However, colposcopic evaluation of diethylstilbestrol-exposed women may be confusing because the physician is frequently presented with findings that in unexposed women are usually associated with cervical intraepithelial neoplasia. In our article the prevalence of abnormal cytologic findings was 9%, and in only half of these patients was a histologically confirmed low-grade cervical intraepithelial neoplasia and vaginal intraepithelial neoplasia diagnosed. These observations suggest a perilous role of colposcopic evaluation and biopsies in inexperienced hands, and we cited three previous reports with similar views.[1-3]

In the literature diverse reasons can be found to explain the different interpretation of colposcopic findings in DES-exposed individuals and in nonexposed patients. Stafl and Mattingly[2] considered the process of "arrested" immature metaplasia in DES-exposed women. Conversely, Orr et al.[1] stated that the confusing colposcopic appearances may be caused by "active metaplasia" in the extensive transformation zone, mimicking patterns of cervical intraepithelial neoplasia.

In the Netherlands, we recommend colposcopic evaluation of DES-exposed offspring in regional centers to obtain and maintain expertise. Because distances in the United States are not comparable with those in this country, we can imagine another option.

Trend of cervical cancer in Jewish women

To the Editors: We read carefully the article by Glezerman et al. (Glezerman M, Piura B, Insler V. Cervical cancer in Jewish women. AM J OBSTET GYNECOL 1989; 161:1186-90).

The Results section contains no data with regard to a change of incidence over time nor are there any data with regard to the population base. The statement in the Comment section and final paragraph with regard to a rising trend of cervical cancer in Jewish women is therefore not justified, especially since the supposed trend has been found not to be statistically significant by the authors themselves. The statement on the ethnic distribution also is not based on presented data. It is not clear whether the population referred to in the article consists of the hospital population or the population in the Negev area. Prevalence trends in one hospital do not necessarily reflect incidence trends in the general population. It is therefore important to mention that according to the Israel Cancer Registry, which is known for its high accuracy, the incidence and

the yearly number of new cases of cervical cancer in Israel (approximately 80 new cases per year) did not change during the years referred to in this article.[1]

Today, when the cost of medical care is an important national problem and there are second thoughts about the benefit of routine screening programs for cervical cancer,[2] it seems to us that the authors' recommendation for changing national policy for cervical cancer screening in a low-risk group such as the Israeli Jewish women is not based on sound epidemiologic data and statistical analysis.

Reply

To the Editors: One of the aims of our article was to point to a rising trend of incidence rates for cervical cancer in Jewish women in South Israel. This trend was expected on the basis of an earlier report that was cited in our article and demonstrated high incidence rates of preinvasive lesions of the uterine cervix among young Jewish women in Israel.[1] We stated that this trend had not reached statistical significance when compared with the population increase. Today, we have 140 Jewish women with invasive cervical cancer in our tumor registry, which covers complete data for the South of Israel. These patients were entered during a period of 30 years. Of these, 30.7% of cases were diagnosed during the past 5 years. In our Gynecological Tumor Registry, the percentage of living patients with invasive cervical cancer today equals those living with ovarian cancer (28% for each malignancy). We have been alerted by these facts.

As for other comments made by Drs. Ben Baruch and Menczer, they may want to again read our article. In the Material and methods section we have presented data concerning our population base and in Table II we have presented data on the ethnic distribution of our population. Moreover, we have elaborated on the unique position of our hospital being the only major health care center for South Israel. Virtually all patients from this defined geographic area are treated at our hospital, a well-known fact within the Israeli medical community. It is true therefore that prevalence trends and incidence rates at our hospital indeed reflect the population base that we serve. Drs. Ben Baruch and Menczer base their comments on one personal communication and on one article questioning the benefit of routine screening for cervical cancer. We feel that their conclusion is unjustified. The value of screening procedures for cervical cancer is well established, and Drs. Ben Baruch and Menczer may want to consult the literature in this regard. In the population of the South of Israel, which is served by our hospital, only one out of every five cases of cervical cancer is diagnosed in a preinvasive state. Given this situation, we feel that screening procedures are urgently needed at least with regard to the South of Israel.

Laboratory identification of the lupus anticoagulant in normal pregnancy and pregnancy-induced hypertension

To the Editors: It was interesting to read the article written by Lockwood et al. (Lockwood CJ, Romero R, Feinberg RF, Clyne LP, Coster B, Hobbins JC. The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population. Am J Obstet Gynecol 1989;161:369-73) because the results could be useful to clarify the complex relationship between lupus anticoagulant and adverse pregnancy outcomes.[1]

However, we are in disagreement concerning the detection of lupus anticoagulant in this article because it was assessed exclusively by activated partial thromboplastin time (aPTT) and mixing studies.

Lupus anticoagulant exhibits considerable laboratory heterogeneity and discordance exists to define the most sensitive and specific test for its identification.[2, 3] The aPTT is the most common assay used to screen for lupus anticoagulant, but its sensitivity varies depending on the test system used.[4] In addition, the aPTT could be normal in pregnant women with lupus anticoagulant because of the elevated factor VIII levels seen in pregnancy.[1] For this reason other screening tests are particulary useful in pregnant women.

In January 1989 we initiated in our laboratory a 2-year prospective study to establish the prevalence of lupus anticoagulant in women with hypertensive disorders of pregnancy or idiopathic intrauterine growth retardation.

Over the first-year period, we studied 20 patients and lupus anticoagulant was detected in five (preliminary results). Two of the five patients with lupus anticoagulant–positive results had normal aPTTs but abnormal kaolin clotting times,[5] abnormal dilute Russell viper venom time corrected by addition of freeze-thawed platelets,[3, 6] and the apparent increase of factor VIII and IX activities as the patients' plasma was assayed at progressively greater dilutions.[7]

On the other hand, Lockwood et al. found a discrepancy between the presence of anticardiolipin antibodies detected by an enzyme-linked immunosorbent assay and the presence of lupus anticoagulant detected by aPTT (2.2% vs 0.27%, respectively). In contrast, in a retrospective study of obstetric history in 21 women with systemic lupus erythematosus we found an equal

relative frequency (47%) of anticardiolipin antibodies and lupus anticoagulant, with an enzyme-linked immunosorbent assay method and a complete panel for lupus anticoagulant (unpublished data).

For these reasons we believe that, to establish the prevalence and biologic significance of lupus anticoagulant in pregnant women, it is mandatory to perform the lupus anticoagulant detection with tests other than the aPTT, such as kaolin clotting time and dilute Russell viper venom time.

Reply

To the Editors: We would like to thank Dr. Riveros and associates for their interest in our study. They assert that the activated partial thromboplastin time (aPTT) "is the most common assay used to screen for lupus anticoagulant, but its sensitivity varies depending on the test system used." Indeed we chose the aPTT with the use of platelet-poor plasma precisely because it is the most commonly used "screening" test for lupus anticoagulant. Prior work has attested to its reliability in this capacity.[1] The use of more sensitive but elaborate functional coagulation assays such as the dilute Russell viper venom time and the kaolin clotting time was deemed inappropriate for a screening study.

Riveros and associates report a 25% prevalence of lupus anticoagulant, presumably utilizing the dilute Russell viper venom time and/or kaolin clotting time, in 20 patients with hypertensive disorders of pregnancy or idiopathic intrauterine growth retardation. This figure appears extraordinarily high, thus suggesting a significant number of false-positive results. In addition, their observation that patients ($n = 21$) with systemic lupus erythematosus had an equal prevalence of lupus anticoagulant and anticardiolipin antibodies (47%) is inconsistent with previous reports. Petri et al.[2] evaluated 60 patients with systemic lupus erythematosus and described a 6.7% prevalence of lupus anticoagulant as ascertained by a Russell viper venom time but a 25% prevalence of anticardiolipin antibodies. Harris et al.[3] evaluated 65 patients with systemic lupus erythematosus and related autoimmune disorders and detected a 49% prevalence of lupus anticoagulant and a 61% prevalence of anticardiolipin antibodies.[3] Thus, while Riveros and colleagues may increase sensitivity with the use of the dilute Russell viper venom time and/or kaolin clotting time, they may also increase the rate of false-positive results.

In short, Riveros and associates are quite correct to assert that the dilute Russell viper venom time and kaolin clotting time are more sensitive indices of the presence of circulating lupus anticoagulant. However, the application of these tests for large-scale screening, while useful, may be impractical.

by Dr. Zuidema (Zuidema LJ, Khan-Dawood F, Dawood MY, Work BA Jr. Hormones and cervical ripening: dehydroepiandrosterone sulfate, estradiol, estriol, and progesterone. AM J OBSTET GYNECOL 1986;155:1252-4) that had stressed the association of the significant elevation of maternal dehydroepiandrosterone sulfate (DHEAS) levels with the changes that precede the onset of labor.

Inspired by Dr. Zuidema's article I carried out an investigative study on the cervical ripening and hormones exclusively in nulliparous women. A total of 53 nulliparous women were included in our study group; all had single vertex presentation and a normal previous pregnancy period.

Maternal venous blood samples were taken just at the onset of the first stage of labor and at the end of the first stage from each woman. In all cases the cervical Bishop scores were <4 when the first blood samples were taken.[1] Plasma DHEAS levels were measured with a radioimmunoassay kit (DPC Coat-A-Count DHEA-SO_4 kit, Diagnostic Products Corp., Los Angeles).

Patient characteristics are summarized in Table I. Statistical analysis of the data indicated significant differences resulting from the maturity of the cervix in nulliparous women (Table II). When grouped in terms of the sex of the fetus the differences in the DHEAS levels of the respective groups (corresponding to either sex) were not significant (Tables III and IV). However, on grouping in terms of the maturity of the cervix (ripe and unripe), the DHEAS levels of the respective groups indicated significant differences (Tables V and VI).

It was thus concluded that the stage of cervical dilatation was the determining factor, and the sex of the fetus was not a factor in causing significant differences between DHEAS levels.

Finally, according to our findings there were no significant chances in estradiol, estriol, and progesterone levels associated with the increase in cervical dilatation, and as was pointed out by Dr. Zuidema et al., the only significant increase was in the DHEAS levels.[2] It can thus be concluded that DHEAS is a hormone that increases during the dilatation period, which is the first stage of labor.

Critical comments on the treatment of tubal pregnancy with prostaglandins

To the Editors: The article by Egarter and Husslein (Egarter C, Husslein P. First successful intrauterine pregnancy after treatment of tubal pregnancy with prostaglandin $F_{2\alpha}$. AM J OBSTET GYNECOL 1989;161:904) describes the treatment of tubal pregnancy with prostaglandins as "highly encouraging." However, the associated burden and dangers for the patient are given little consideration. The injection of prostaglandin $F_{2\alpha}$ in a high dose (up to 10 mg) into the tube,[1] which has an increased blood circulation because of pregnancy, always presents the risk of mistaken intravascular administration that can have fatal results. Serious complications, in some cases fatal, have been reported after the use of intrauterine prostaglandin.[2] In addition, the injection of several milliliters of fluid into a tube already extended by the ectopic pregnancy increases the intratubal pressure and thus the danger of hematoma and tubal rupture. The subsequent 3-day systemic treatment with a prostaglandin E_2 derivative is not quite so dangerous; however, for the patient it is very unpleasant because of lower abdominal pain and other side effects such as nausea and vomiting. Because success of treatment can only be established after a few days, intensive care is necessary. At the same time, the uncertainty of the outcome presents a psychologic strain on the patient.

Considering the side effects already observed with this therapy such as hemodynamic disturbances, lung edema, and laryngospasm, it does not seem justifiable for the authors to evaluate the treatment as "having reduced postoperative morbidity." In the interest of patient safety, we consider it prudent to warn of the dangers of this method, especially when intensive care facilities are inadequate. There are currently other safer methods of treatment, for example, the laparoscopic salpingotomy, that guarantee certain termination of pregnancy without much stress for the patient, also providing a good chance for tubal patency.[3]

Reply

To the Editors: We appreciate the interest of Drs. Dietl and Lippert in our article and would like to address the points they raised in their letter. In the first patients treated with prostaglandins we also injected prostaglandin $F_{2\alpha}$ into the corpus luteum, assuming a direct luteolytic effect would occur. Severe side effects developed in three patients immediately after the intra*ovarian* application of prostaglandin $F_{2\alpha}$ and we indicated this fact by referring to the literature.[1] As soon

Table I. Prostaglandin $F_{2\alpha}$ treatment in patients with an initial β-subunit of human chorionic gonadotropin level <2500 mIU/ml (n = 120)

	No.	%
Success	101	84.2
Failure	19	15.8
Hysterosalpingogram (n = 40)		
Tubal patency	35	88
Tubal occlusion	5	12

as we omitted the intra*ovarian* prostaglandin $F_{2\alpha}$ dose and drew special attention to a slow application of the intra*tubal* dose with concomitant surveillance of blood pressure and heart frequency, no immediate adverse drug reactions occurred.

Drs. Dietl and Lippert stated that application of several milliliters of fluid might lead to tubal rupture caused by increased tubal pressure. The occurrence of this event is extremely unlikely because we only apply 1.5 to 2 ml; we never observed a single case with this side effect in our large series. Moreover, as Lang et al.[2] recently demonstrated, an intratubal instillation of up to 20 ml is apparently not associated with any such consequences.

It is true that the success of this treatment can only be established in some cases after a few days. Additional hormone parameters[3] and our growing experience will probably overcome this psychologic burden. However, other methods such as laparoscopic salpingotomy also do not guarantee definite termination of pregnancy as Vermesh et al.[4] showed with a 5.3% failure rate. In these cases the final resolution of ectopic pregnancy is not only delayed but also associated with a second operative procedure. Moreover, the laparoscopic management requires technical facilities as well as operative skills that are lacking in many gynecologic centers.

We believe that our final success rate of 84.2% in patients with an initial β-subunit of human chorionic gonadotropin level <2500 mIU/ml serum (Table I)[5] seems to justify the ongoing research with prostaglandin. The involved risks of the relatively simple application of prostaglandin $F_{2\alpha}$ are reasonable if our safety recommendations are used as follows: (1) aspiration *before* application to avoid erroneous intravasal injection, (2) strict supervision during application, (3) determinations of postoperative β-subunit of human chorionic gonadotropin values. Nonetheless, a prospective randomized comparison of prostaglandin treatment and laparoscopic operation would be of special interest.

Ovulation prediction from cyclic changes in salivary electrical conductivity

To the Editors: To enable large-scale studies aimed at improvement of present diagnostic contraceptive methods, we have introduced luteinizing hormone (LH) determination in saliva and have shown a sufficiently reliable correlation between the salivary midcycle LH peak and ovulation confirmed by ultrasonography.[1-3] Unpublished data indicate a well-correlated relationship between cyclic changes in salivary electrical conductivity measured with a Philips conductometer and LH peaks. Albrecht et al.[4] have reported such a relationship for salivary electrical resistance and developed the CUE ovulation predictor for use in infertility treatment.[5-7] When a device that was easily handled became available for conductivity determination dissolved solids tester (DIST 4), it was tested together with the CUE for its potential in ovulation prediction. This letter reports on first results from 30 cycles comparing the data obtained with the CUE and the DIST.

For details regarding participants see Table I.

Basal body temperature was taken rectally with a mercury thermometer and the CUE and DIST were used immediately afterward. Only the oral CUE readings were taken. After this reading several milliliters of early morning saliva (i.e., before eating, drinking, smoking, etc.) were collected in a beaker fit to the sensor of the DIST and readings noted in the basal body temperature chart. Saliva was then transferred into plastic tubes and kept frozen until laboratory determination of LH. Salivary LH has been determined radioimmunologically by modifying a commercially available LH radioimmunoassay kit as previously described in detail.[1]

The CUE devices used in this study were purchased from Zetek, Inc. (Aurora, Colo.). The instrument measures salivary electrical resistance (ohm). A peak is said to occur 5 to 7 days before ovulation. The relevant peak is defined as a higher reading followed by at least two

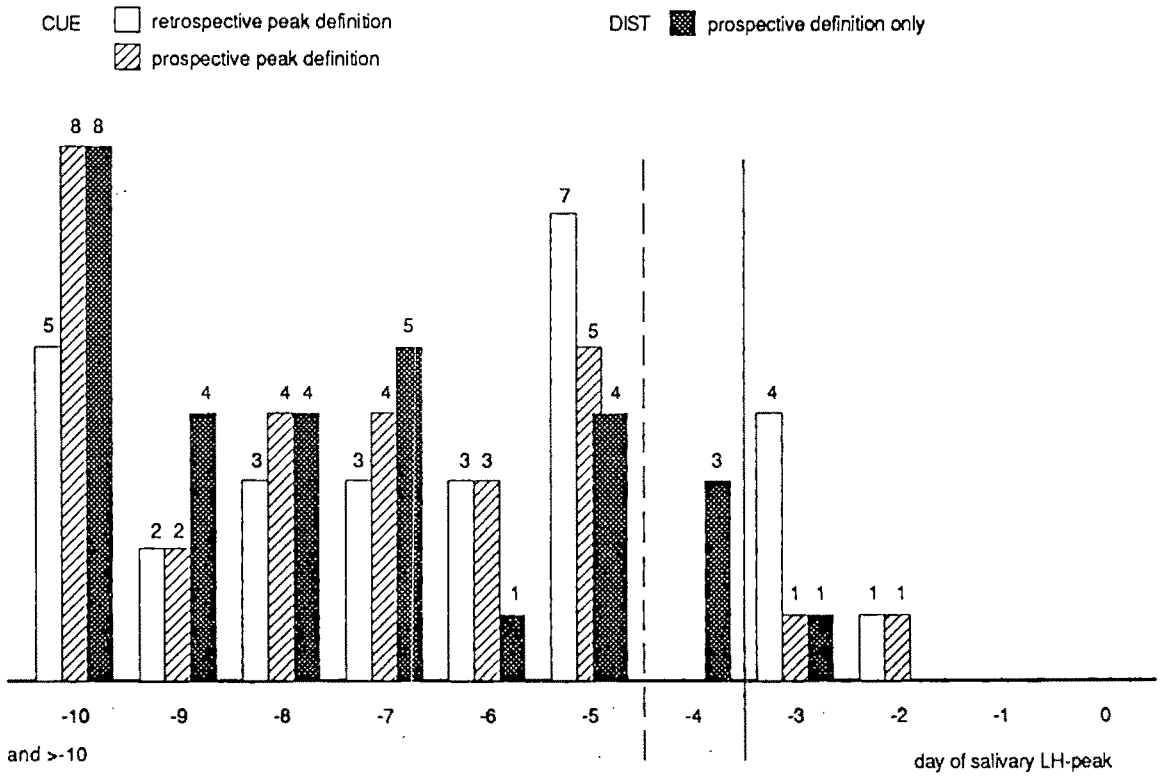

Fig. 1. Ovulation prediction in relation to salivary LH peak.

Table I. Participants and cycles

No. of nulliparous volunteers	*Age (yr)*	*No. of cycles*	*Cycle length (days)*	*Follicular phase (days)*	*Luteal phase (days)*
5	23.1 ± 2.95	30	29.7 ± 3.47	16.6 ± 2.86	13.1 ± 1.85

Table II. Predictive capacity of the CUE ovulation predictor and the DIST conductivity meter (N = 30)

	Cycles		*Ovulation prediction before salivary LH peak*			*Overall theoretical reliability (%)*	*Additionally diagnosed days of preovulatory infertility*
	Interpretable	*Not interpretable*	*≥5 days*	*4 days*	*≤3 days*		
CUE							
Retrospective peak definition	29	1	24	0	5	80	3.57 ± 2.63
Prospective peak definition	28	2	26	0	2	86.7	2.81 ± 1.92
DIST (only prospective peak definition)	30	0	26	3	1	96.7	2.86 ± 1.86

lower ones, the first one being at least 10% lower than the peak.

The DIST (World Precision Instruments, Inc., New Haven, Conn.) is a new pocket-size conductometer (microseconds). Results are displayed digitally as with the CUE. Total dissolved solids units are equivalent to parts per million of sodium chloride. For use in native saliva the DIST 4 (range 19,000 μs, resolution 100 μs,

accuracy 2%) proved to be appropriate. The testers were purchased from Austro-Merck (Vienna). No previous experience with this device exists in the field of our study.

Thirty cycles with complete data have been evaluated. With the retrospective definition for a CUE peak provided by the manufacturer an average of 3.57 ± 2.63 days of additional preovulatory infertility could be diagnosed. However, in six of 30 cycles (20%) infertility has been signaled for too long with regard for contraceptive purposes. In one case the CUE did not predict ovulation at all; in four cases the peak occurred only 3 days and in one case 2 days before the LH peak. In a search for a prospective rule for the CUE peak (e.g., as exceeding the mean by a certain margin), the range between 0.97 and 1.1 SDs above the mean was checked. Only a cutoff point of 0.97 gave reasonable results. With this altered rule for defining the peak as the first value above the mean + 0.97 SD, an additional 2.81 ± 1.92 days of preovulatory infertility could be diagnosed with four wrong indications: two predictions were too late and twice no peak was detectable.

Applying a similar peak rule to the DIST readings, interpretable results were obtained in all 30 cycles, and 2.86 ± 1.86 additional days of preovulatory infertility could be diagnosed. In only one case prediction came too late (day −3). Results are shown in Table II and Fig. 1.

As previously stated,[8] future fertility indicators should be able to predict ovulation at least 4 or 5 to 6 days in advance, taking into consideration the time sperm can retain their fertilizing capacity depending on the cervical factor.[9, 10] The reliability of a prediction 4 days before the salivary LH peak must be closely examined in field trials, although it has been reported as sufficient in the literature.[5, 6, 10, 11] We certainly do not believe that 3 days would be an adequate warning.[12]

The aim of the CUE is to predict the best time to conceive and is not to be used in contraception. The problem lies in the definition of the peak, which is only detectable 2 days *after* its occurrence. For contraceptive purposes the peak must be recognizable the very day it appears. We have tried to achieve this with a prospective concept which, however, yielded an overall theoretical reliability of only 86.7% (Table II). By contrast the DIST readings were interpretable in all 30 cycles, occurring too late in only one, thus resulting in a theoretical reliability of 96.7%. Whereas the numbers of additionally diagnosed preovulatory infertile days for the CUE and for the DIST are of the same order of magnitude, the substantial difference in the reliability of the devices allows only for the DIST to be considered for further investigation aimed at decisively improving diagnostic family planning methods. The underlying physiologic feature for the observed correlation between the DIST peaks and salivary LH peaks have not yet been fully explored, even though characteristic cyclic changes of salivary electrolytes are beyond doubt. Further studies with the DIST regarding the underlying mechanism and the reliability of predicting ovulation are currently under way in our laboratory.

Amniotic fluid midtrimester delta optical density measurements at 450 nm in Rh disease

To the Editors: I read with interest the recent article by Ananth and Queenan (Ananth U, Queenan JT. Does

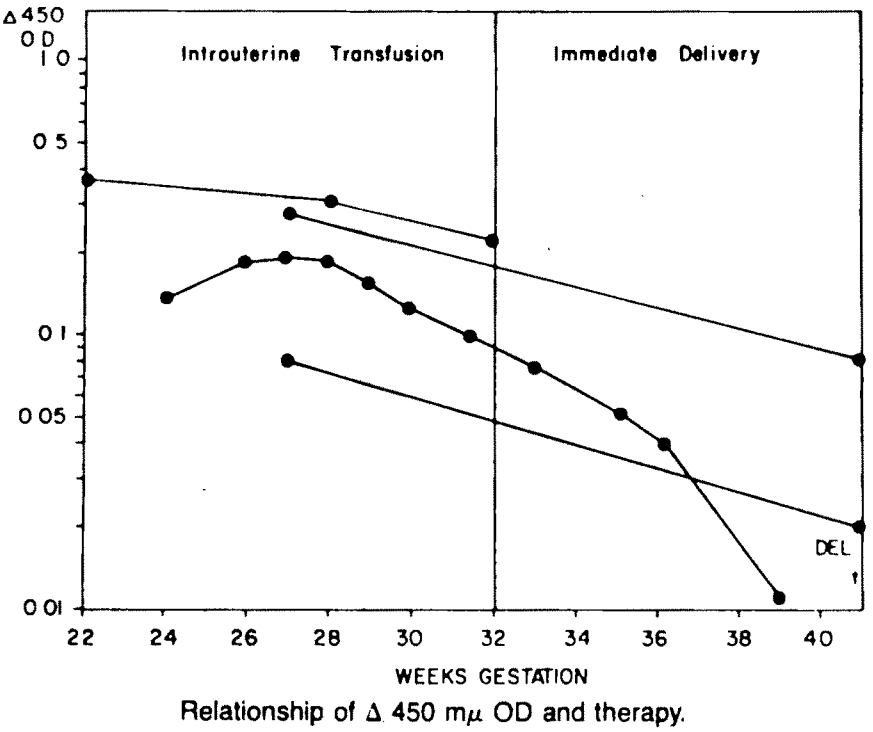

Fig. 1. Relationship between ΔOD_{450} and gestational age. Reprinted by permission from the *Southern Medical Journal* (1979;72:241-2).

midtrimester ΔOD_{450} of amniotic fluid reflect severity of Rh disease? AM J OBSTET GYNECOL 1989;161:47-9) regarding midtrimester amniotic fluid values of delta optical density measurements at 450 nm (ΔOD_{450}) in Rh disease. In their Fig. 1 they clearly show that in some patients the hemolytic process is under way between 16 and 20 weeks' gestation. However, I am a little disturbed by the statement that a single amniotic fluid ΔOD_{450} value >0.15 or an amniotic fluid trend rising above 0.15 indicates severe disease. In this study no ΔOD values are reported from unaffected pregnancies beyond 23 weeks' gestation.

I recommend that obstetricians exercise caution in the use of the cutoff point of 0.15 between 23 and 27 weeks' gestation. In 1979 I reported[1] two cases in which the ΔOD rose between 24 and 27 weeks' gestation from 0.140 to 0.200. A plot of the ΔODs of one patient is shown in Fig. 1. As you can see, the ΔOD plateaued at 27 to 28 weeks' gestation and then gradually declined to term. Both mothers were delivered of unaffected Rh-negative infants. Therefore I suggest that the recommendations of Ananth and Queenan not include the terminal weeks of the midtrimester.

George H. Nelson, PhD, MD

Department of Obstetrics and Gynecology, University of South Carolina, School of Medicine, Two Richland Medical Park, Suite 103, Columbia, SC 29203

REFERENCE

Reply

To the Editors: In normal pregnancies (no erythroblastosis fetalis) the amniotic fluid delta optical density values at 450 nm (ΔOD_{450}) follows a rising trend from 16 to 23 weeks' gestation.[1,2] The values then level off. The normal amniotic fluid ΔOD_{450} values in the third trimester show a downward trend from week 27 until term. This trend forms the basis for the management for Rh disease in the third trimester. The accuracy of predicting severe Rh disease in the third trimester is excellent in our study and in others.[2,3,4] However, it has been shown in our study and in others[1,5] that Liley's graph cannot be extrapolated into the second trimester. Investigators have shown a poor correlation between amniotic fluid ΔOD_{450} values and the fetal hemoglobin in the midtrimester.[5] Therefore, some advocate the use of percutaneous umbilical blood sampling in all Rh-immunized pregnancies.[5]

This study pertains to amniotic fluid ΔOD_{450} values from 16 to 20 weeks' gestation. In the cases studied: a

value >0.15 was associated with severe erythroblastosis fetalis and values of <0.09 were associated with mild or no Rh disease. The ΔOD_{450} values between 0.09 and 0.15 require further evaluation to determine the trend.

Dr. Nelson comments that he has seen two patients in whom the amniotic fluid ΔOD_{450} ran between 24 and 27 weeks' gestation from 0.14 to 0.20. These infants were Rh-negative and unaffected.

We agree that >0.15 values are possible at that stage of pregnancy. Our study is focused on the period of 16 to 20 weeks' gestation when genetic amniocentesis is done. This is the time when normal physiologic fetal hemolysis is just beginning and the values are therefore lower.

Our recommendations do not pertain to the period between 21 and 27 weeks' gestation. And of course, Liley's graph works well thereafter.

OBSTETRICS/GYNECOLOGY

Here's a practice opportunity we believe you would enjoy. Six family physicians, two surgeons, an optometrist and a clinical psychologist in a busy practice in sister cities on the Red River in southern North Dakota/western Minnesota. The clinic facility is new with ample room for additional staff. Hospital is a modern 95 bed hospital with over 360 deliveries a year. Two of the physicians on staff are currently doing C-sections.

Wahpeton/Breckenridge has a combined population of 15,000 with a patient draw area of over 40,000. Wahpeton is the home of the ND State College of Science and each community has public and parochial primary education.

Will join a 250 physician multispecialty group affiliated with a 400 bed level II hospital which has a NACHRI designated Children's Hospital and a 24 bed level III ICN.

For further information regarding this excellent practice opportunity please contact Robert Ostmo, M.D., 227 6th St. N., Breckenridge, MN 56520 or call 1-218-643-7813.

Life.

It's our life's work.

If your mission in life is to practice the ideals of medicine without administrative demands, we invite your inquiry.

Group Health Plan in St. Louis is a staff model HMO that promotes the ideals of private practice while freeing doctors from the financial baggage of the private practitioner.

Group Health Plan isn't for every physician. Just for those few who want to practice medicine without compromise.

For an interview please talk with the Medical Recruiter at (314) 993-5955. Or write Group Health Plan, 11475 Olde Cabin Road, St. Louis, Mo. 63141. An equal opportunity employer.

GROUP HEALTH PLAN

PHYSICIAN TO COORDINATE OB/GYN RESIDENCY PROGRAM

The Allentown Hospital — Lehigh Valley Hospital Center (TAH-LVHC), an 830-bed tertiary care teaching hospital in Allentown, Pennsylvania, is seeking a board certified physician to supervise and direct the residents in the hospital's fully approved, free-standing OB/GYN Residency Program. The hospital is approved for two residents each year and will soon be seeking a third. All residents within the program are United States medical graduates.

The OB/GYN Department has physicians practicing in all three subspecialties: maternal/fetal medicine, gynecologic oncology and reproductive endocrinology. Four neonatologists run the 20-bed Level III NICU. TAH-LVHC is a regional Level III Perinatal Center. The hospital is in the process of designing a high-risk obstetrics unit.

We are seeking a physician strongly committed to education to coordinate the residency program and also direct OB/GYN ambulatory care. Clinic patients account for 500 of the hospital's 3,300 births each year. The OB/GYN clinic runs five days a week, and is a source of approximately 50 new OB patients each month.

Our hospital is located in Allentown, which has the advantage of being a cosmopolitan city whose suburbs quickly merge into rolling Pennsylvania farmland. We serve a population of close to one million people, and are located one hour from Philadelphia and one and one-half hours from New York City. Interested candidates please send curriculum vitae in confidence to Sze-ya Yeh, M.D., Chair, Department of OB/GYN, c/o HealthSearch, 50 College Drive, Room 327, Allentown, PA 18104.

Be Where You Want To Be

At **Southern California Permanente Medical Group (SCPMG)**, you can be exactly where you want to be — in terms of your professional practice and in terms of lifestyle.

We are a physician-managed, multi-specialty medical group serving the nation's largest healthcare organization.

Our continued growth has created new opportunities for **Obstetricians/Gynecologists** to join one of our Obstetric practices. To qualify you must be Board Certified/Eligible and proficient in modern techniques. University affiliation and research is encouraged.

You'll have a choice of professional environments ranging from a 250-bed community hospital to a major teaching facility in a number of prime Southern California locations.

We offer • **Paid Malpractice Insurance** • **Predictable Hours** • **Guaranteed Practice and Income.**

Perinatologist Search Committee
1500 Forest Glen Road
Silver Spring, MD 20910

Postdoctoral Training Program in Medical Genetics

The Interdepartmental Medical Genetics Program at Stanford University School of Medicine provides advanced clinical and/or research training related to human inherited disease. Well-represented areas of the program include:

- The molecular basis of heritable disorders including polygenic and multifactorial diseases.
- Chromosome structure and function.
- Genome and gene mapping.
- The development of methods to manipulate and to study large fragments of DNA.
- Developing animal models and new treatment modalities of human genetic disease by homologous recombination.

Individuals with an MD, PhD, or equivalent degree are eligible for this three-year program which includes an extended period of research training with one of twenty-six training faculty and the opportunity to pursue applied training in clinical genetics, clinical cytogenetics, or molecular genetics in an ABMG-accredited setting. Minority individuals are especially encouraged to apply. For information and application forms, contact:

Uta Francke, M.D.
Departments of Genetics and Pediatrics
Howard Hughes Medical Institute
Stanford, California 94305-5428

FACULTY POSITIONS CALIFORNIA

LOS ANGELES COUNTY/ OLIVE VIEW MEDICAL CENTER

DIRECTOR OF MATERNAL- FETAL MEDICINE: Beautiful new state-of-the-art UCLA affiliated teaching hospital seeks director of a three-member division. Candidate should be a senior, experienced leader, board certified in maternal-fetal medicine, with investigative abilities. The position includes faculty appointment at UCLA School of Medicine.

GENERAL OBSTETRICIAN/GYNECOLOGIST: Board eligible/certified Obstetrician/Gynecologist to join twelve full-time hospital based academic physicians. Assignments include obstetrics, gynecology and outpatient services with emphasis on resident teaching/supervision. Clinical research encouraged. The position requires a faculty appointment at UCLA School of Medicine.

Olive View Medical Center is a 377-bed acute care facility located in the San Fernando Valley 25 miles north of the UCLA campus in Westwood. It serves a catchment population in excess of two million. It is an integral part of the UCLA student and residency training program in obstetrics and gynecology. Twelve obstetric and gynecology residents are assigned to Olive View. Over 7,000 high risk obstetrical patients are delivered yearly supported by a fully staffed antenatal testing unit, obstetrical anesthesia and neonatalogy/NICU coverage as well as full internal medicine, surgery, pediatrics and emergency medicine services.

UNIVERSITY OF OXFORD

NUFFIELD PROFESSORSHIP OF OBSTETRICS AND GYNAECOLOGY

The electors intend to proceed to an election to the Nuffield Professorship of Obstetrics and Gynaecology, which falls vacant on 1 October 1990, upon the retirement of Sir Alexander Turnbull. The stipend of the professorship is currently £41,025.

Applications (ten copies, or one from overseas candidates), naming three referees, should be received not later than 20 August 1990 by the Registrar, University Offices, Wellington Square, Oxford, OX1, 2JD, from whom further particulars may be obtained.

The University is an Equal Opportunity Employer

MATERNAL-FETAL MEDICINE

The Department of Obstetrics and Gynecology at the University of Tennessee Medical Center at Knoxville is currently recruiting one or two additional BC/BE specialists in Maternal-Fetal Medicine.

This is the chance to join a young, growing, dynamic program which encourages active participation in resident and outreach education and offers ample opportunity for basic and clinical research. More than 700 procedures are done monthly in the Department's autonomous Obstetrical Ultrasound and Antenatal Assessment Unit. Constuction of a new Labor and Delivery suite is expected to be completed in January of 1991.

A highly competitive compensation package, coupled with relatively low malpractice insurance, and proximity to many recreational facilities in beautiful East Tennessee makes this an extremely attractive opportunity for the person interested in combining a rewarding academic career and a full family life.

Academic rank is commensurate with qualifications and experience. Interested persons should send C.V. or inquiries to:

Candidates are being sought for the position of Chair of the Department of Obstetrics/Gynecology, James H. Quillen College of Medicine, East Tennessee State University, a community-based medical school which graduated its ninth class in May 1990. The Department currently has 12 full-time faculty, active research programs, an established faculty practice plan which includes the subspecialities of maternal fetal medicine and reproductive endocrinology. It also includes 30 part-time and volunteer faculty in this and neighboring communities. The Department has significant teaching responsibilities in undergraduate, graduate, and continuing medical education. The College of Medicine is located in a prosperous, beautiful Southern Appalachian Mountain community, with a population base of over one million in the immediate referral area. Candidates must be board certified in Obstetrics and Gynecology with proven expertise in teaching, research, and administration. Interested applicants should contact Steven L. Berk, M.D., Chairman, Obstetrics/Gynecology Search Committee, Department of Internal Medicine, P. O. Box 21,160A, Johnson City, Tennessee 37614, (615) 929-6282. ETSU is an AA/EOE.

ELKO REGIONAL MEDICAL CENTER

762 - 14th Street Elko, Nevada 89801 (702) 738-3111

OBSTETRICIAN/GYNECOLOGIST

Nevada's oldest multi-specialty clinic seeks BE/BC OB/GYN to join two other OB-GYN's and Nurse Midwife in very busy practice. Lucrative opportunity for full range of specialty practice. THE DEPARTMENT OF OBSTETRICS AND GYNECOLOGY UNIVERSITY OF WISCONSIN MEDICAL SCHOOL MILWAUKEE CLINICAL CAMPUS

is seeking applicants for two (2) additional full-time faculty positions in MATERNAL FETAL MEDICINE to participate in the development of a new women's health center and academic program. The current faculty includes two perinatologists.

Sinai Samaritan Medical Center is in the process of consolidating its obstetrical and gynecological services in a redesigned facility in downtown Milwaukee. The department has the largest perinatal service in Wisconsin (5200 deliveries), has a dedicated antenatal testing and perinatal ultrasonography (including doppler) unit, and is preparing for an expansion in prenatal diagnostic services (including CVS). The department has a midwifery service and an adolescent pregnancy service. The department has an urban care mission while ready to expand into an up-to-date tertiary care perinatal referral center for Southeastern Wisconsin.

Qualifications include board candidacy or certification in maternal-fetal medicine and a commitment to teaching residents, medical students, and clinical research.

San Francisco, CA 94110
(415) 641-6543

CHAIRMAN, DEPARTMENT OF OBSTETRICS AND GYNECOLOGY

Chairman, Department of Obstetrics and Gynecology, St. Paul-Ramsey Medical Center (SPRMC) and Ramsey Clinic (RC). SPRMC, located in St. Paul, Minnesota, is a major teaching affiliate of the University of Minnesota and a major referral and trauma center. Ramsey Clinic, serving St. Paul-Ramsey Medical Center, is a multispecialty group practice with an extensive regional referral and outreach program. Minimum academic preparation must include M.D. degree and board-certification in obstetrics and gynecology. Candidate should have post-residency professional experience and will be expected to administer a Department of Obstetrics and Gynecology within a group practice and direct faculty and residents in service, education and research. The salary will be commensurate with experience. The candidate is also expected to qualify for appointments at the Professor or Associate Professor level at the University of Minnesota Department of Obstetrics and Gynecology. Qualifications for the University of Minnesota Associate Professorship include professional distinction in research and writing, and demonstrated effectiveness in teaching and advising. Qualifications for the Professorship are those of Associate Professor, plus a national reputation in research, and evidence of leadership in candidate's professional field.

The University of Minnesota, St. Paul-Ramsey Medical Center and Ramsey Clinic are equal opportunity educators and employers and specifically invite and encourage applications from women and minorities.

Closing date for application is October 15, 1990. Address inquiries to:
Kent B. Crossley, M.D., Professor
Department of Medicine
Chairman, Search Committee
for Chief of Obstetrics and Gynecology
St. Paul-Ramsey Medical Center/Ramsey Clinic
St. Paul, Minnesota 55101
(612) 221-3486

University of California, Irvine, College of Medicine, OB/GYN. Assistant Professor-In-Residence (M.D.), board eligible/certified in Obstetrics and Gynecology with subspecialty training in Gynecologic Urology with extensive pelvic surgery experience. Strong research focus in genuine stress incontinence. Duties include functioning as Director of Ambulatory Care Service; medical student, resident, and postgraduate teaching; clinical service supervision; clinical and laboratory research.

UCI is an Equal Opportunity/Affirmative Action Employer.

FACULTY POSITIONS

MATERNAL FETAL MEDICINE

The Department of Obstetrics and Gynecology at the University of Illinois College of Medicine at Chicago is currently seeking faculty in the Perinatal Division at Assistant or Associate Professor level. Qualified individuals will be responsible for providing tertiary care to high-risk patients, instructing medical students, residents, and fellows in the field, and performing research in their areas of expertise. Special interests in infectious disease, diabetes, or prenatal diagnosis desired. Certification or eligibility in the subspecialty is required.

Send C.V. to:

Antonio Scommegna, M.D.
Professor and Head, Department of OB/GYN
(M/C 808)
University of Illinois College of Medicine at Chicago
840 South Wood Street
Chicago, Illinois 60612
Tel: (312) 996-0469
or
Steven Warsof, M.D.
Director, Division of Maternal-Fetal Medicine

(The University of Illinois is an Equal Opportunity/ Affirmative Action Employer)

AMBULATORY CARE DIRECTOR

The University of Louisville Department of Obstetrics & Gynecology is seeking a Ambulatory Care Director with a Faculty appointment rank open. This position will have the responsibility for oversight, teaching and pioneering work in outpatient screening methods, hysteroscopy and hysteroscopic surgery, laparoscopy, pelviscopic surgery, and laser surgery. The Director will be administratively in charge of all ambulatory and outreach programs in which our residents and medical students participate, as well as the hospital based ambulatory surgery activities of this department. These responsibilities will include protocol development, control and quality assurance, intradepartmental relationships and liaison with other departments and the hospital. The Director will oversee all medical aspects of the teaching clinics and will share coverage with other faculty.

Requires: An active candidate or Diplomate of the American Board of Obstetrics and Gynecology and 2 years experience minimum.

Introducing the

Year Book of Infertility®

This time-saving guide book makes it easy for you to keep current in your field. Each volume represents the year's most significant developments as reported in more than 800 journals and periodicals published worldwide. These selections are condensed to roughly a page in length, so you get all essential facts at a glance.

More importantly, the distinguished physician editors provide thoughtful, probing commentaries that explore the significance of each article while evaluating its practical implications for day-to-day practice.

Save hours of reading and research time and get expert guidance with this invaluable reference!

These books are published annually. For the convenience of its customers, Year Book enters each purchaser as a subscriber to future volumes and sends annual announcements of each volume approximately two months before publication. The new volume will be shipped upon publication unless you complete and return the cancellation notice attached to the announcement and it is received by Year Book within the time indicated (approximately 20 days after your receipt of the announcement). You may cancel your subscription at any time. The new volume may be examined on approval for 30 days and returned for full credit. Year Book will remove your name as a subscriber. Return postage is guaranteed by Year Book to the Postal Service.

To Subscribe:
Simply fill out this coupon and send it to us at the address shown.

Or,
for faster service, call our TOLL-FREE number:
1-800-426-4545

Prepaid orders are shipped postage free; add $3.50 per order to cover handling. Other orders will be billed a shipping and handling charge. IL, MA, TN residents will be billed appropriate sales tax. Prices are quoted in U.S. dollars. Canadian orders billed in U.S. funds. All prices subject to change without notice.

[X] ***YES!***
I know it's vital that I stay informed. Please rush me the most recent issue of the *Year Book of Infertility* (IN-89) for $54.95.

21- and 28-day regimens

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

Smooth Sailing!

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28 day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

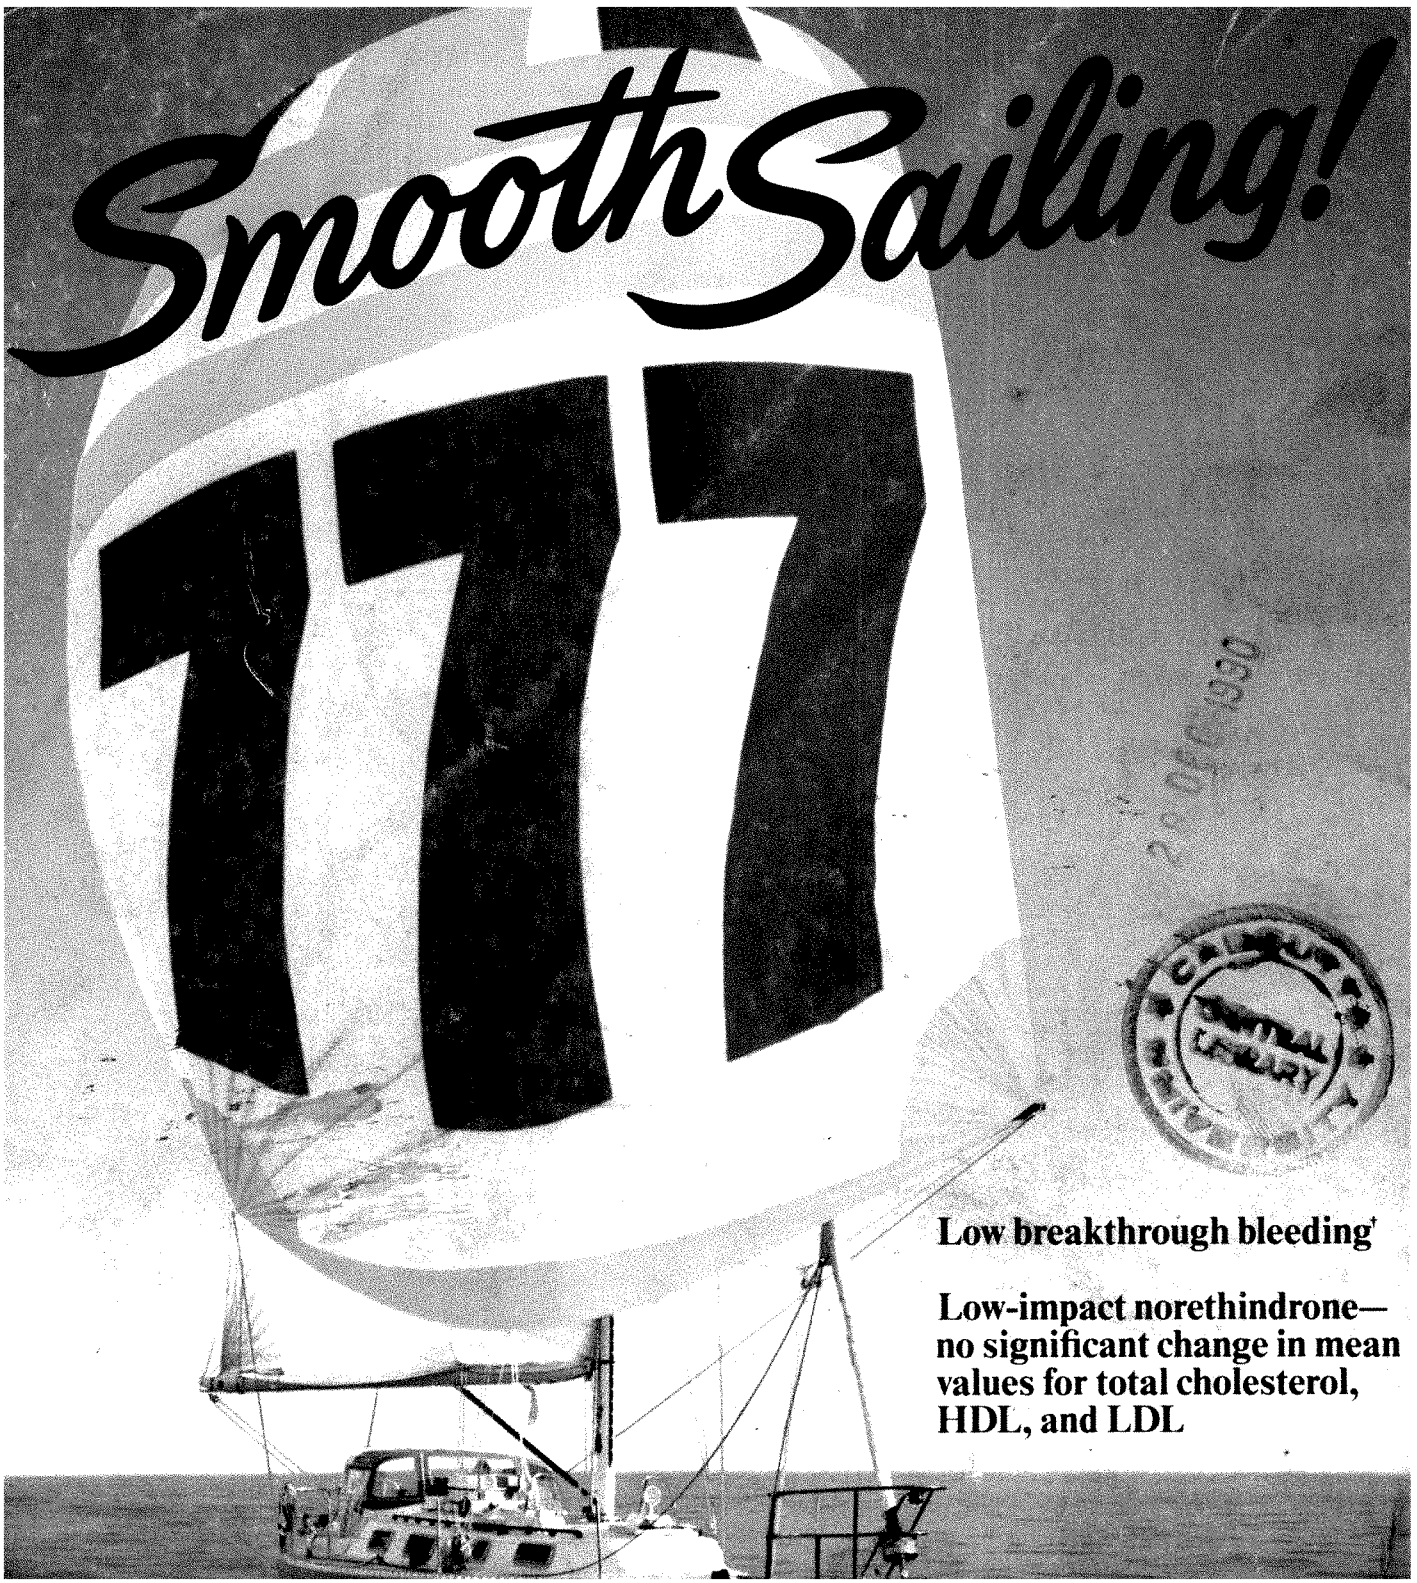
INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids, however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert.**



ADVERSE REACTIONS: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis.

OVERDOSAGE: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

Active young female in late teens looking for lasting relationship with OC. Concerned about side effects of acne and bloating.
Career - oriented woman in mid-20s wants to find right OC. Wishes to avoid side effects such as weight gain, headache, and depression. Open to raising a family — but later.

A personalized approach to oral contraceptives.

Because Tri-Norinyl is uniquely phased for all phases of a woman's reproductive life, it's ideal for a wide range of patient types:

Older, nonsmoking patients restarting contraception, because Tri-Norinyl is the only multiphasic with low-impact norethindrone that *lowers* progestin in late cycle to minimize overall hormonal and metabolic impact.

Career-oriented patients delaying childbearing, because reduced progestin helps minimize side effects that can disrupt daily life, such as weight gain, headache, and depression.

Younger patients just starting contraception, because low-impact norethindrone lowers the risk of acne and bloating, and is increased at mid-cycle, to provide enhanced endometrial support when breakthrough bleeding is most likely to occur.

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL®

Uniquely phased for all phases of a woman's reproductive life

Committed to the OB/GYN and women's healthcare

SYNTEX

SYNTEX LABORATORIES, INC
PALO ALTO, CA 94304

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease.
Please see next page for brief summary of prescribing information. © 1990 Syntex Laboratories, Inc. 814-H2-172-90

TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

BRIEF SUMMARY

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 yellow-green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 yellow-green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 7 inert orange tablets)
BREVICON® 21-Day Tablets (norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
BREVICON® 28-Day Tablets (21 norethindrone 0.5 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 35 21-Day Tablets (norethindrone 1 mg with ethinyl estradiol 0.035 mg)
NORINYL® 1 + 35 28-Day Tablets (21 norethindrone 1 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 50 21-Day Tablets (norethindrone 1 mg with mestranol 0.05 mg)
NORINYL® 1 + 50 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.05 mg tablets followed by 7 inert tablets)
NOR-Q.D.® (norethindrone) Tablets 0.35 mg
ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications: Prevention of pregnancy.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions:
- Thrombophlebitis or thromboembolic disorders
- A past history of deep vein thrombophlebitis or thromboembolic disorders
- Cerebral vascular or coronary artery disease
- Known or suspected carcinoma of the breast
- Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia
- Undiagnosed abnormal genital bleeding
- Cholestatic jaundice of pregnancy or jaundice with prior pill use
- Hepatic adenomas, carcinomas or benign liver tumors
- Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial Infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS**, section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have an increase in mortality greater than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long term (>8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out.

Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T4 concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING**.

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section):

• Thrombophlebitis • Arterial thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemorrhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenomas, carcinomas or benign liver tumors.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed:

• Mesenteric thrombosis • Retinal thrombosis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related:

• Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spotting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminution in lactation when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepening) • Intolerance to contact lenses.

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted:

• Pre-menstrual syndrome • Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness • Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis.

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

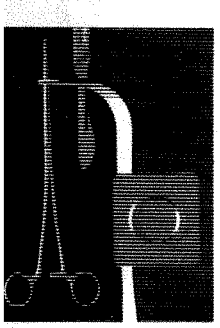
NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses:

• Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea

Effects related to inhibition of ovulation:



• Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use:

• Decreased incidence of fibroadenomas and fibrocystic disease of the breast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

Rev. August 1989

SYNTEX

Count on

CEFOTAN® IM/IV
(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

Intravenous or Intramuscular Use
EF SUMMARY

ICATIONS AND USAGE
:ATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the wing infections when caused by susceptible strains of the designated organisms:
ıary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus ıbilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia ɣeri,* and *Morganella morganii*).
er respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *ɔhylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* luding ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
ı and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* cies (excluding enterococci), and *E coli.*
ecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, ratus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *tococcus* and *Peptostreptococcus* species*).
a-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, ɐetaiotaomicron*).
e and joint infections caused by *Staphylococcus aureus.**
icacy for this organism in this organ system was studied in fewer than ten infections.
pecimens for bacteriological examination should be obtained in order to isolate and identify sative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted ıre results of susceptibility studies are known; however, once these results become available, the biotic treatment should be adjusted accordingly.
cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other ous infections in which the causative organism has not been identified, it is possible to use CEFOTAN comitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown e synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. dosage recommended in the labeling of both antibiotics may be given and depends on the severity ıe infection and the patient's condition.
E: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully ıitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is onged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. ough, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that hrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
IPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain ıoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transhral surgery, biliary tract surgery, and gastrointestinal surgery).
ıe prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In pats undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping ıe umbilical cord.
there are signs and symptoms of infection, specimens for culture should be obtained for identifica- of the causative organism so that appropriate therapeutic measures may be initiated.
ITRAINDICATIONS
OTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.
ıINGS
ıre therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the ent has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, ıcillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. biotics should be administered with caution to any patient who has demonstrated some form of ɣy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. ous acute hypersensitivity reactions may require epinephrine and other emergency measures. eudomembranous colitis has been reported with the use of cephalosporins (and other broad-ɛtrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop rhea in association with antibiotic use.
eatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overvth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of biotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro. ild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be ıaged with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not reıd by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for anti-c-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.
CAUTIONS
IERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overvth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection s occur during therapy, appropriate measures should be taken.
common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in hrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutrial state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at and exogenous vitamin K administered as indicated.
:FOTAN should be used with caution in individuals with a history of gastrointestinal disease, pararly colitis.
ORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction 'acterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, ı is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the stion of alcoholic beverages following the administration of CEFOTAN.
IG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given e, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an ıoglycoside.
IG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur Benedict's or Fehling's solution.
ı with other cephalosporins, high concentrations of cefotetan may interfere with measurement of ım and urine creatinine levels by Jaffe reaction and produce false increases in the levels of tinine reported.
CINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in ıals have not been performed to evaluate carcinogenic potential, no mutagenic potential of tetan was found in standard laboratory tests.
ɛfotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

CEFOTAN® (cefotetan disodium)

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.
Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.
DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.
Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.
When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

Females: 0.9 × value for males

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.
HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

Metabolism of cocaine by human placentas: Implications for fetal exposure

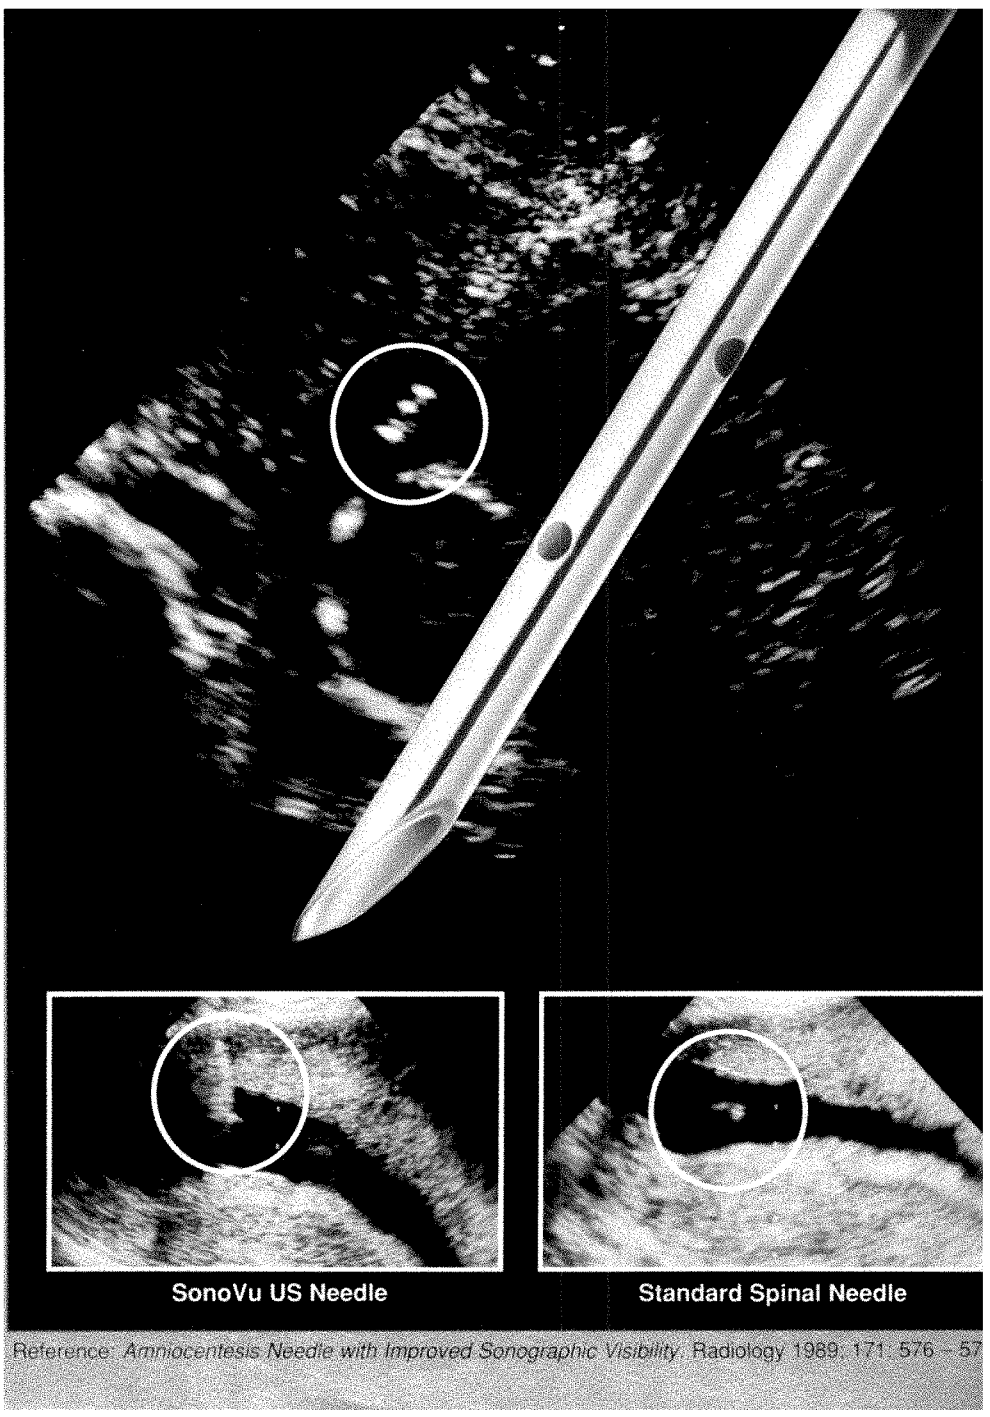
Daniel A. Roe, BS, Bertis B. Little, PhD, Roger E. Bawdon, PhD, and Larry C. G
Dallas, Texas

Human placental microsomes metabolized cocaine in vitro, suggesting a protective maternal-fetal physiology.

Survival rates of monoamniotic twins do not decrease after 30 w gestation

Stephen R. Carr, MD, Michael P. Aronson, MD, and Donald R. Coustan, MD
Providence, Rhode Island

An advantage to early delivery in monoamniotic twin pregnancies could not be dem because fetal survival rates in 24 sets of monoamniotic twins did not decrease after gestation.



Ultrasonographic evaluation of uteroplacental blood flow patterns abnormally located and adherent placentas

Glenford P. Guy, MD, David B. Peisner, MD, and Ilan E. Timor-Tritsch, MD
New York, New York

Patients with placenta previa and pulsatile placental lacunar flow had a higher risk loss, abnormally adherent placenta, and cesarean hysterectomy.

Transplacental transfer of zidovudine in the near-term pregnant baboon 728
Gary D. V. Hankins, MD, Curtis L. Lowery, Jr., MD, Richard T. Scott, MD, W. Robert Morrow, MD, K. D. Carey, DVM, PhD, M. Michelle Leland, DVM, and Edward V. Colvin, MD
Lackland Air Force Base and San Antonio, Texas, and Birmingham, Alabama

After oral administration of azidothymidine to pregnant baboons, both azidothymidine and 5'-glucuronide azidothymidine showed a concentration gradient; the level increased from maternal serum to fetal serum to amniotic fluid.

A protocol for managing severe preeclampsia in the second trimester 733
Baha M. Sibai, MD, Sherif Akl, MD, Fiona Fairlie, MD, and Michael Moretti, MD
Memphis, Tennessee

Expectant management with aggressive maternal and fetal monitoring improves perinatal outcome in a select group of patients with severe preeclampsia in the second trimester.

Catastrophic complications of previous cesarean section 738
Cynthia Chazotte, MD, and Wayne R. Cohen, MD
Bronx, New York

The risk of serious morbidity or mortality in this series of 711 pregnancies complicated by previous cesarean section was 2.4%.

Antibiotic therapy in preterm premature rupture of membranes: A randomized, prospective, double-blind trial 743
Matthew M. Johnston, MD, Luis Sanchez-Ramos, MD, Arthur J. Vaughn, MD, Mark W. Todd, PharmD, and Guy I. Benrubi, MD
Jacksonville, Florida

Antibiotic use in preterm premature rupture of the membranes decreases the maternal infection rate, prolongs the delivery latency period, and results in improved neonatal outcome.

Prenatal Testing? Vivigen!

When you need prenatal genetic testing results, choose Vivigen. Physicians worldwide select Vivigen for its high quality:

- chromosome analysis of amniotic fluid and chorionic villi
- biochemical testing of maternal serum AFP, AFP^3 and AFAFP
- molecular genetic testing including cystic fibrosis carrier detection and prenatal diagnosis by DNA analysis

With seven geneticists certified by the American Board of Medical Genetics on staff, expert consultation is always available. Enhance the quality of medical care you provide your patients; rely on Vivigen for thorough, accurate and timely prenatal genetic testing. Turn-around time averages just **seven** days for amniotic fluid chromosome analyses.

For more information on prenatal genetic testing, call 1-800-VIVIGEN.

Effect of tocolytic agents on fetal umbilical velocimetry 748
Jeffery W. Wright, MD, Robert M. Patterson, MD, Louis E. Ridgway III, MD, and Michael D. Berkus, MD
San Antonio, Texas

Umbilical artery systolic/diastolic ratios decline in patients treated with terbutaline, but not in those treated with magnesium.

Does the umbilical artery systolic/diastolic ratio reflect flow or acidosis? 751
Joshua A. Copel, MD, Donald Schlafer, DVM, MS, PhD, Richard Wentworth, PhD, Kathy Belanger, PhD, Lois Kreitzer, MS, John C. Hobbins, MD, and Peter W. Nathanielsz, MD, PhD
New Haven, Connecticut, and Ithaca, New York

The placentas of fetal sheep were acutely embolized and it was demonstrated that reductions in flow occurred before changes in the umbilical systolic/diastolic ratio.

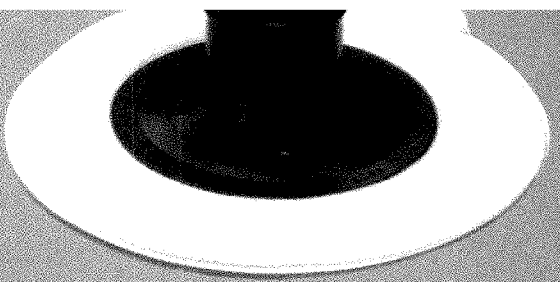
Infection and labor. VI. Prevalence, microbiology, and clinical significance of intraamniotic infection in twin gestations with preterm labor 757
Roberto Romero, MD, Fayek Shamma, MD, Cecilia Avila, MD, Carlos Jimenez, MD, Robert Callahan, BS, Jose Nores, MD, Moshe Mazor, MD, Carol A. Brekus, MSN, CNM, and John C. Hobbins, MD
New Haven, Connecticut

Microbial invasion of the amniotic cavity occurred in 10.8% of patients with twin gestations and preterm labor.

Superiority of the four-quadrant sum over the single-deepest-pocket technique in ultrasonographic identification of abnormal amniotic fluid volumes 762
Thomas R. Moore, MD
San Diego, California

The maximum-vertical-pocket technique of amniotic fluid assessment had low sensitivity and positive predictive power when compared with the four-quadrant amniotic fluid index.

Randomized investigation of magnesium sulfate for prevention of preterm birth 767
Susan M. Cox, MD, M. Lynne Sherman, RN, and Kenneth J. Leveno, MD
Dallas, Texas



In a randomized controlled study of 156 pregnancies complicated by preterm labor magnesium sulfate was not an effective tocolytic agent.

Fetal gastroschisis and omphalocele: Is cesarean section the best mode of delivery? 773
David F. Lewis, MD, Craig V. Towers, MD, Thomas J. Garite, MD, David N. Jackson, MD, Michael P. Nageotte, MD, and Carol A. Major, MD
Orange, Long Beach, and Pasadena, California

Mode of delivery of infants with abdominal wall defects was analyzed, and no difference in neonatal morbidity or mortality was identified.

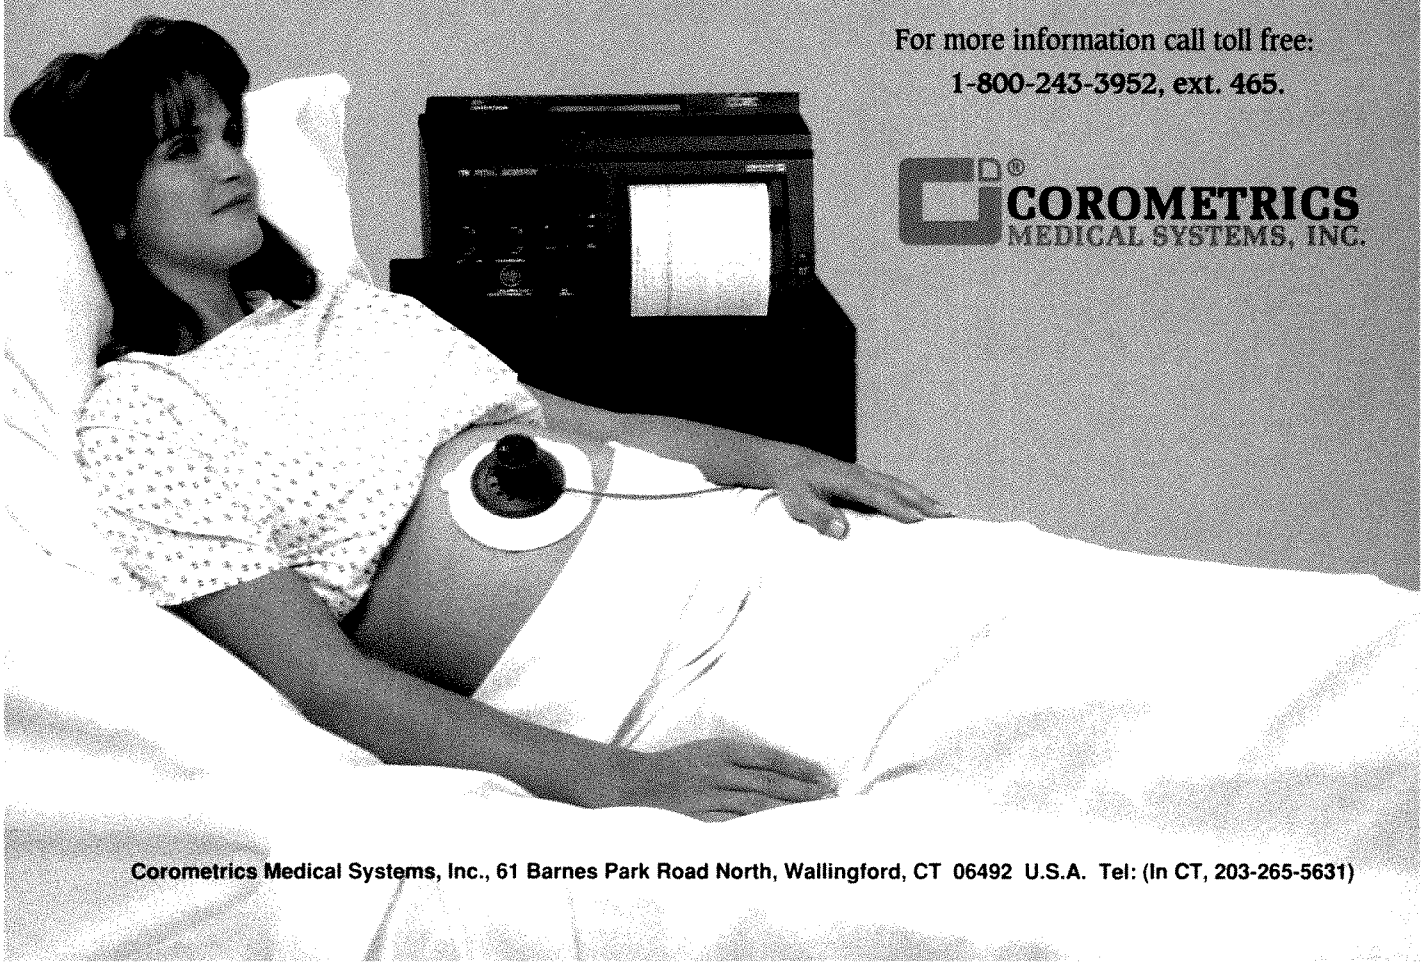
- **Reduces Nursing Time**
- **Improves Data Integrity**



Corometrics' unique new Beltless Tocotransducer virtually eliminates instability and inconvenience. A disposable adhesive baseplate holds the transducer securely in place. This system provides reliable, useful readings even during patient position changes, sitting or walking.

Not only do patients enjoy freedom from the constrictive belt, but also nurses appreciate how little attention is required to obtain a clear, continuous reading.

For more information call toll free:
1-800-243-3952, ext. 465.

Acute fetal hemodynamic alterations after intrauterine transfusion for treatment of severe red blood cell alloimmunization 776
Kenneth J. Moise, Jr., MD, Giancarlo Mari, MD, David J. Fisher, MD, James C. Huhta, MD, Lorraine E. Cano, RN, and Robert J. Carpenter, Jr., MD
Houston, Texas, and Philadelphia, Pennsylvania

Combined intravascular-intraperitoneal transfusions for treatment of severe red blood cell alloimmunization were associated with a fall in fetal cardiac output and a rise in umbilical venous pressure.

Postinjection kinetics of antepartum Rh immune globulin 784
Frank R. Witter, MD, Rosetta S. Shirey, MS, Suzy L. Nicol, BS, and Paul M. Ness, MD
Baltimore, Maryland

Administration of 300 μg of Rh immune globulin at 28 weeks consistently produces detectable antibodies at 42 days after injection but not at 84 days after injection.

Magnesium sulfate and promethazine do not interact to cause hypotension in gravid ewes 787
Kenneth L. Pollack, MD, David H. Chestnut, MD, Carl P. Weiner, MD, Christine S. Thompson, and Craig S. DeBruyn
Iowa City, Iowa

Magnesium sulfate and promethazine did not interact to cause maternal hypotension in normovolemic gravid ewes.

Uterine hyperstimulation after low-dose prostaglandin E_2 therapy: Tocolytic treatment in 181 cases 794
Christian H. Egarter, MD, Peter W. Husslein, MD, and William F. Rayburn, MD
Vienna, Austria, and Omaha, Nebraska

Uterine hyperstimulation after local prostaglandin E_2 therapy is an uncommon finding and rapidly reversible with β_2-adrenergic therapy.

Prevalence of use of cocaine and other substances in an obstetric population 797
Cristina Matera, MD, Wendy B. Warren, MD, Maureen Moomjy, MD, Daniel J. Fink, MD, and Harold E. Fox, MD
New York, New York

Five hundred nine consecutive urine toxicologic screens in patients admitted to an urban university hospital labor room revealed a 10% prevalence of cocaine use.

A comparison of the effect of epidural, general, and no anesthesia on funic acid-base values by stage of labor and type of delivery 802
Jaye M. Shyken, MD, James S. Smeltzer, MD, L. V. Baxi, MD, Karin J. Blakemore, MD, Steven E. Ambrose, MD, and Roy H. Petrie, MD, ScD
St. Louis, Missouri

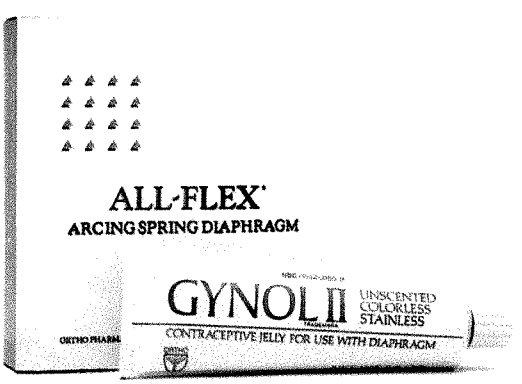
Epidural anesthesia offers no clear-cut metabolic advantage to the normal, term fetus undergoing vaginal delivery or cesarean section.

(Contents continued on page 13A)

To be continued...

Continuation...an excellent indicator of patient satisfaction.

The Ortho ALL-FLEX* Arcing Spring Diaphragm



- ☐ Easy to insert and position
- ☐ Easy to clean and maintain
- ☐ Easy to use with unscented, colorless, stainless GYNOL II* (2% nonoxynol-9) Contraceptive Jelly
- ☐ The combination for continuation—with 4 out of 5 patients continuing after 1 year†

Continuation...it's one reason why physicians continue to make ORTHO ALL-FLEX and GYNOL II the #1 prescribed diaphragm combination in America.‡

Ortho ALL-FLEX*

Arcing Spring

D I A P H R A G M

†Number of patients continuing the method for 12 consecutive months; data on file, Ortho Pharmaceutical Corporation.

‡Data on file, Ortho Pharmaceutical Corporation.

Consult the patient brochure for information on toxic shock syndrome (TSS) and wearing time.

Contents continued from page 11A

Effect of uterine contractility and maternal hypotension on prolonged decelerations after bupivacaine epidural anesthesia 808
Ralph M. Steiger, MD, and Michael P. Nageotte, MD
Orange and Long Beach, California

Patients with prolonged decelerations after bupivacaine epidural anesthesia were more likely to have uterine hypertonus and as likely to have maternal hypotension as control subjects.

The effect of amnioinfusion on uterine pressure and activity: A preliminary report 813
Marvin D. Posner, MD, Susan A. Ballagh, MD, and Richard H. Paul, MD
Los Angeles, California

Uterine tone and activity are compared before, during, and after intrapartum transcervical saline solution amnioinfusion, and a case of uterine hypertonus is discussed.

Comparison of umbilical artery pH and 5-minute Apgar score in the low-birth-weight and very-low-birth-weight infant 818
Craig F. Stark, MD, Ronald S. Gibbs, MD, and Walter L. Freedman, MD
Denver, Colorado

In low-birth-weight infants 5-minute Apgar score varies with birth weight, and both umbilical artery pH and Apgar score are influenced by small-for-gestational-age and appropriate-for-gestational-age categorization.

Preterm delivery: A risk factor for retained placenta 823
Roberto Romero, MD, Yu Chiung Hsu, MD, Apostolos P. Athanassiadis, MD, Zion Hagay, MD, Cecilia Avila, MD, Jose Nores, MD, Alistair Roberts, MD, Moshe Mazor, MD, and John C. Hobbins, MD
New Haven, Connecticut

Preterm delivery is a risk factor for retained placenta.

Fetal umbilical artery Doppler response to graded maternal aerobic exercise and subsequent maternal mean arterial blood pressure: Predictive value for pregnancy-induced hypertension 826
R. F. Hume, Jr., MD, MAJ, MC, USA, J. D. Bowie, MD, C. McCoy, MD, P. C. Magarelli, MD, PhD, M. Gall, RN, B. S. Hertzberg, MD, B. A. Carroll, MD, and A. P. Killam, MD
Durham, North Carolina

The fetal umbilical artery Doppler velocimetry response to graded maternal aerobic exercise at 28 weeks' gestation predicts pregnancy-induced hypertension and preeclampsia.

The Shirodkar operation: A reappraisal 830
Faith J. Frieden, MD, Steven A. Ordorica, MD, Iffath A. Hoskins, MD, and Bruce K. Young, MD
New York, New York

A review of 66 consecutive Shirodkar procedures by one surgeon shows this treatment of cervical incompetence to be safe, effective, and compatible with vaginal birth.

(Contents continued on page 14A)

Contents continued from page 13A

The effect of mode of delivery on the perinatal outcome in fetuses with abdominable wall defects 833
Michael Moretti, MD, Aldo Khoury, MD, Jaime Rodriquez, MD, Thom Lobe, MD, David Shaver, MD, and Baha Sibai, MD
Memphis, Tennessee

A study of 125 infants with abdominal wall defects shows no adverse affects from vaginal delivery on perinatal or long-term outcome.

Perinatal survival with expectant management of midtrimester rupture of membranes 838
Carol A. Major, MD, and John L. Kitzmiller, MD
San Francisco, California

The perinatal survival among 70 patients with midtrimester rupture of membranes managed expectantly was 63%; 68% of survivors had normal neurologic and physical development at 1 year of follow-up.

Double-blind comparison of intravaginal prostaglandin E_2 gel and "chip" for preinduction cervical ripening 845
Carl V. Smith, MD, William F. Rayburn, MD, Robert E. Connor, RPh, Glen R. Fredstrom, RPh, and Corinne B. Phillips, MD
Omaha, Nebraska

A single dose of either prostaglandin E_2 gel or "chip" promoted cervical ripening; a greater risk of uterine hyperstimulation was related to use of the "chip."

Vaginal breech delivery: A five-year prospective evaluation of a protocol using computed tomographic pelvimetry 848
Stefanie Schupp Christian, MD, Kim Brady, MD, John A. Read, MD, and Jerome N Kopelman, MD
Tacoma, Washington

Computed tomographic pelvimetry is an effective tool in the assessment for vaginal delivery of the singleton term frank breech fetus.

The incidence of significant fetomaternal hemorrhage in patients undergoing cesarean section 855
Nathalie Feldman, MD, Amanda Skoll, MD, and Baha Sibai, MD
Memphis, Tennessee

Fetomaternal hemorrhage of >30 ml was detected in 2.5% of 199 patients who had undergone cesarean section for all indications.

Prediction of risk for preterm delivery by ultrasonographic measurement of cervical length 859
H. Frank Andersen, MD, Clark E. Nugent, MD, Suzanne D. Wanty, RN, MSN, and Robert H. Hayashi, MD
Ann Arbor, Michigan

Cervical effacement, measured by endovaginal ultrasonography or manual vaginal examination, was significantly associated with preterm delivery.

Contents

Is indicated or spontaneous preterm delivery more advantageous for the fetus? 868
John Owen, MD, Susan L. Baker, MD, John C. Hauth, MD, Robert L. Goldenberg, MD, Richard O. Davis, MD, and Rachel L. Copper, MSN
Birmingham, Alabama

A case-control study showed no survival advantage in fetuses who underwent indicated preterm delivery.

Evaluation of a risk scoring system as a predictor of preterm birth in an indigent population 873
John Owen, MD, Robert L. Goldenberg, MD, Richard O. Davis, MD, Katharine A. Kirk, PhD, and Rachel L. Copper, MSN
Birmingham, Alabama

The clinical utility of a risk scoring system for the prediction of spontaneous preterm birth in an indigent population is limited.

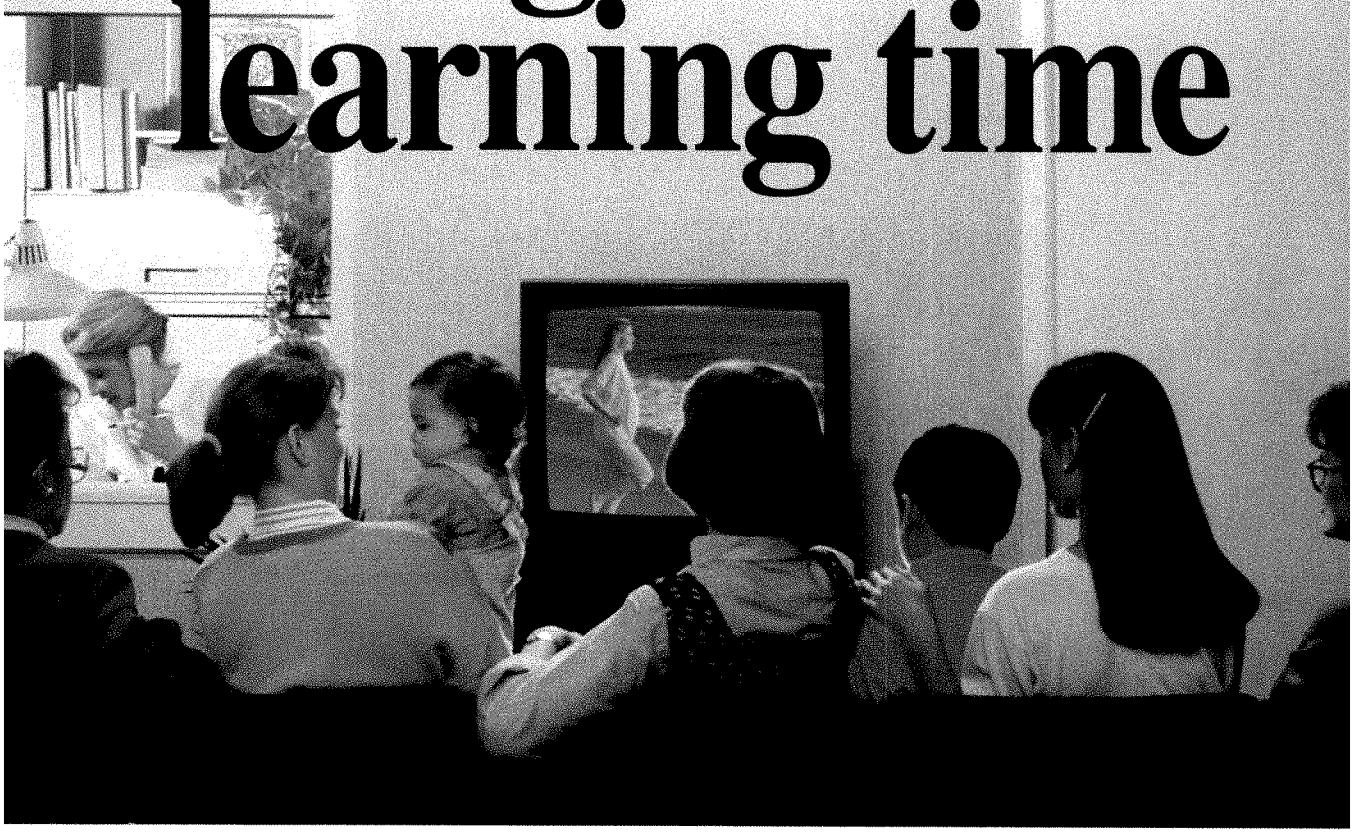
A prospective randomized comparison of oral terbutaline and magnesium oxide for the maintenance of tocolysis 879
Louis E. Ridgway III, MD, Kevin Muise, MD, Jeffrey W. Wright, MD, Robert M. Patterson, MD, and Edward R. Newton, MD
San Antonio, Texas

In a randomized study oral magnesium was as effective as terbutaline in the maintenance of tocolysis, with fewer side effects and at a lower cost.

Awaiting cervical change for the diagnosis of preterm labor does not compromise the efficacy of ritodrine tocolysis 882
Gregory O. Utter, MD, Sharon L. Dooley, MD, Ralph K. Tamura, MD, and Michael L. Socol, MD
Chicago, Illinois

Awaiting change in cervical effacement and/or dilation in patients dilated <3 cm on admission does not compromise tocolytic efficacy.

Gram stain results from amniocentesis in patients with preterm premature rupture of membranes—Comparison of maternal and fetal characteristics 887
Tamerou Asrat, MD, Michael P. Nageotte, MD, Thomas J. Garite, MD, Steven E. Gocke, MD, and Wendy Dorchester, MPH
Orange and Long Beach, California



Patients with preterm premature rupture of membranes and positive amniotic fluid Gram stains had higher incidences of elevated fetal heart rate and nonreactive fetal heart rate tracings.

Adjusting the loading dose of magnesium sulfate for tocolysis 889
Jeffrey W. Wright, MD, Louis E. Ridgway III, MD, and Robert M. Patterson, MD
San Antonio, Texas

A method for estimating an adjusted loading dose for magnesium sulfate was established, and this adjusted loading dose was tested in the treatment of preterm labor.

We turn waiting time into learning time

At no cost to you or your patients, HealthLink Television can turn waiting time into a positive educational experience.

We'll install a TV, videodisc player, patient information material, and hours of healthcare programming, turning your waiting room into an informative extension of your practice.

Affiliated with Lifetime Medical Television and produced in cooperation with the HealthLink Obstetrics/Gynecology Advisory Board, HealthLink Television provides women with the information they want and the quality you expect.

For a free enrollment kit and program samples, call 1-800-969-LINK.

Infants of diabetic mothers with accelerated fetal growth by ultrasonography: Are they all alike? 893
James D. Keller, MD, Boyd E. Metzger, MD, Sharon L. Dooley, MD, Ralph K. Tamura, MD, Rudy E. Sabbagha, MD, and Norbert Freinkel, MD
Chicago, Illinois

Evaluation of longitudinal ultrasonographic examination and metabolic data in 47 infants of diabetic mothers reveals a growth pattern that raises questions concerning the uniformity of diabetic macrosomia.

Prevalence and etiology of respiratory distress in infants of diabetic mothers: Predictive value of fetal lung maturation tests 898
Siri L. Kjos, MD, Frans J. Walther, MD, PhD, Martin Montoro, MD, Richard H. Paul, MD, Fidelia Diaz, MA, and Mary Stabler, BS
Los Angeles, California

Surfactant-deficient respiratory distress syndrome occurred in 5 of 526 infants of diabetic mothers; the lecithin/sphingomyelin ratio, phosphatidylglycerol, and optical density (650 nm) had 100% sensitivity and 100% negative predictive value.

The relationship between maternal serum and amniotic fluid α-fetoprotein in women undergoing early amniocentesis 903
Cynthia G. Brumfield, MD, Gretchen A. Cloud, MS, Richard O. Davis, MD, Sara C. Finley, MD, John C. Hauth, MD, and Larry Boots, PhD
Birmingham, Alabama

No correlation was found between α-fetoprotein levels in the maternal serum and amniotic fluid in pregnancies undergoing early amniocentesis from 12 to 14 weeks' gestation.

Perinatal outcome of forty-nine pregnancies complicated by acardiac twinning 907
Thomas R. Moore, MD, Scott Gale, MD, and Kurt Benirschke, MD
San Diego, California

Outcome of pregnancy complicated by acardiac twinning was related to the relative size of the acardiac to the normal co-twin.

Embryofetal effects of pentamidine isethionate administered to pregnant Sprague-Dawley rats 912
Timothy W. Harstad, MD, Bertis B. Little, PhD, Roger E. Bawdon, PhD, Kraig Knoll, BS, Daniel Roe, BS, and Larry C. Gilstrap III, MD
Dallas, Texas

In this study we evaluated the embryofetal effects of pentamidine and found an increased early embryo loss but no evidence of congenital anomalies.

(Contents continued on page 18A)

Contents continued from page 17A

An evaluation of the chorionic villus sampling learning curve 917
Richard K. Silver, MD, Scott N. MacGregor, DO, John S. Sholl, MD, Edward D. Hobart, and Jody K. Waldee, RN
Evanston, Illnois

A low fetal loss rate observed during the initial period of a chorionic villus sampling program may not reflect the acquisition of expertise associated with cumulative experience.

The association of single umbilical artery with cytogenetically abnormal pregnancies 922
Devereux N. Saller, Jr., MD, Carol Lynn Keene, MD, Chen-Chih J. Sun, MD, and Stuart Schwartz, PhD
Baltimore, Maryland

Single umbilical artery is associated with certain karyotypic abnormalities including trisomy 13 and trisomy 18 but not trisomy 21.

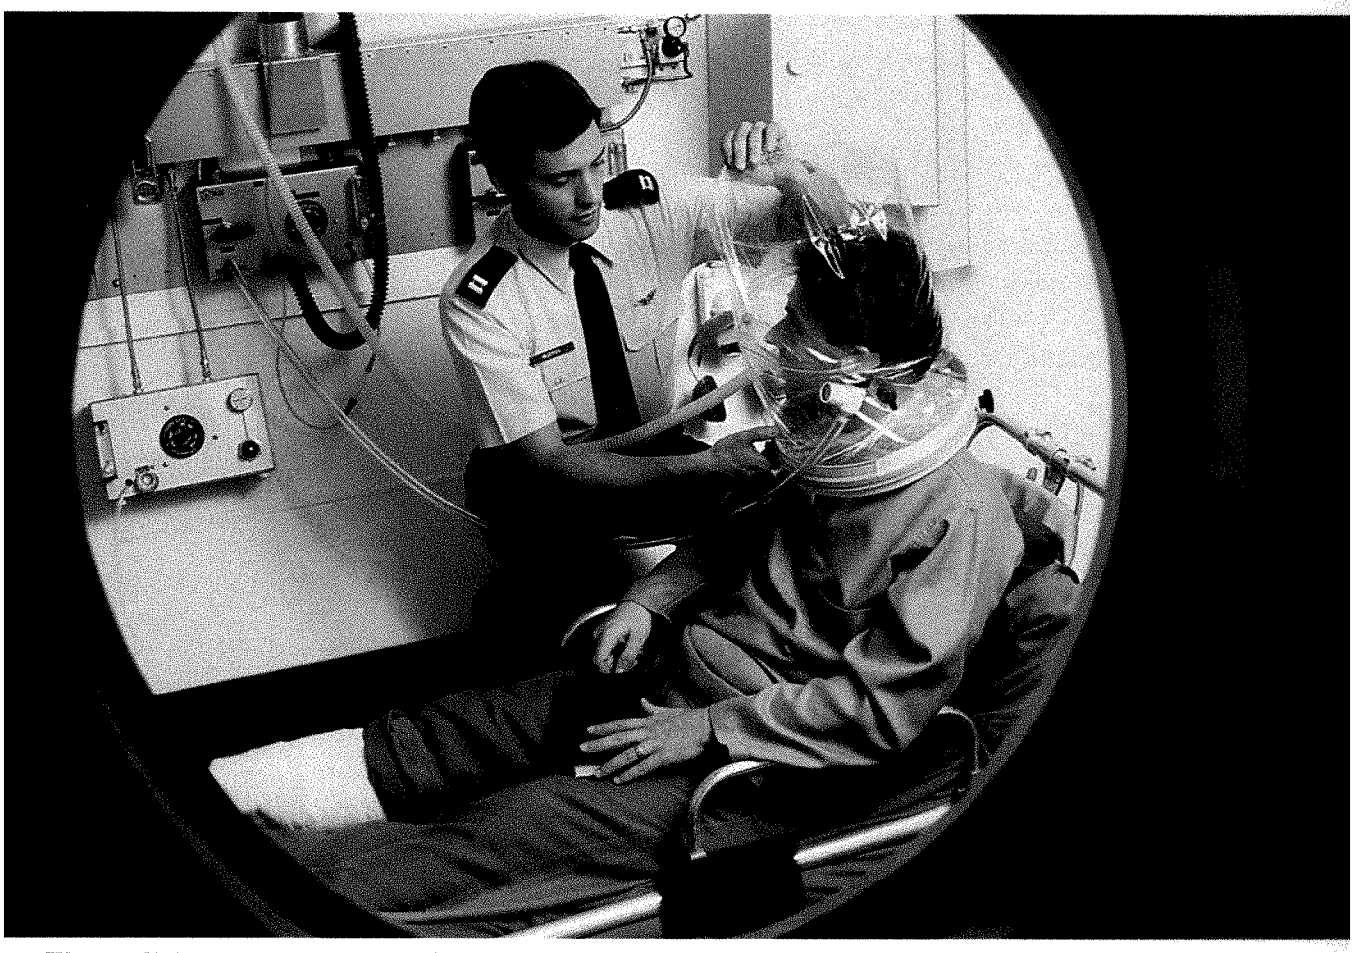
Transcervical chorionic villus sampling and amniocentesis: A comparison of reliability, culture findings, and fetal outcome 926
J. E. Ferguson II, MD, Dan J. Vick, BA, Joan S. Hogge, MS, and W. Allen Hogge, MD
Charlottesville, Virginia

Pregnancy loss rates were similar after chorionic villus sampling and amniocentesis, but procedure and culture failures were less likely when amniocentesis was used.

Second-trimester placental biopsy for rapid fetal karyotyping 931
A. D. Cameron, MB, ChB, A. M. Mathers, MB, ChB, S. Wisdom, MB, ChB, J. Johnstone, RGN, J. R. M. MacKenzie, MB, ChB, J. J. Walker, MB, ChB, S. J. Imrie, BSc, G. W. Lowther, BSc, DipRCPath, and J. M. Connor, BSc, MD
Glasgow, Scotland

Second-trimester placental biopsy was found to be a useful procedure for establishing fetal karyotypes in pregnancies at significant risk of chromosomal abnormality.

The association of maternal floor infarction of the placenta with adverse perinatal outcome 935
Robert L. Andres, MD, William Kuyper, BA, Robert Resnik, MD, Kathleen M. Piacquadio, MD, and Kurt Benirschke, MD
San Diego, California



Maternal floor infarction of the placenta is associated with recurrent fetal death, intrauterine growth retardation, and preterm delivery.

Placental transfer of cefazolin and piperacillin in pregnancies remote from term complicated by Rh isoimmunization 938
Charles E. L. Brown, MD, James T. Christmas, MD, and Roger E. Bawdon, PhD
Dallas, Texas

Both cefazolin and piperacillin crossed the placenta promptly in pregnancies remote from term; the presence of hydrops did not impair transfer of cefazolin.

LAST YEAR, 12 DOCTORS GAVE UP PRIVATE PRACTICE FOR A CHALLENGING NEW CAREER.

They didn't give up medicine. They just started practicing it in a more xhilarating environment.

An environment that affords them many tangible benefits. Like a diverse practice, nlimited access to medical specialities, and financial security. Plus a lot of ıtangibles. Like a comfortable lifestyle, an opportunity for worldwide experiences nd the respect that goes along with being an Air Force officer.

Of course, to enter an environment this rewarding, they did have to give up a few ıings. Like rent, equipment expenses, malpractice insurance, payrolls and tility bills.

Now, you may be intrigued by such a unique opportunity. But like any ood medical professional, you'd probably like a complete case history. ɔ call 1-800-423-USAF. Or send your curriculum vitae to Colonel William . Patterson, United States Air Force/RSH, Randolph ir Force Base, Texas 78150-5421.

AIM HIGH.

Ultrastructural aspects of preeclampsia. II. Mitochondrial changes 943
Douglas R. Shanklin, MD, and Baha M. Sibai, MD
Memphis, Tennessee

Direct-vision uterine biopsy specimens obtained at cesarean section or at cesarean section hysterectomy showed extensive myometrial mitochondrial injury in women with preeclampsia but not in normotensive patients; similar mitocondrial injury was found in liver and skin, indicative of a systemic metabolic disorder.

Absence of evidence of pulmonary maturity at amniocentesis in term infants of diabetic mothers 954
Emmanuel O. Ojomo, MD, and Donald R. Coustan, MD
Providence, Rhode Island

Review of 153 charts of diabetic mothers revealed that a significant proportion of women with gestational diabetes (~21%) and overt diabetes (~20%) had absence of phosphatidylglycerol at amniocentesis at term.

Liver histopathologic findings in women with sickle cell disease given prophylactic transfusion during pregnancy 958
Edward Yeomans, MD, Thomas W. Lowe, MD, Edwin H. Eigenbrodt, MD, and F. Gary Cunningham, MD
Dallas, Texas

Forty women with sickle cell disease who underwent prophylactic erythrocyte transfusions during pregnancy had hepatic iron deposition but no evidence of irreversible liver damage.

Comparison of a rapid enzyme-linked immunosorbent assay test and the Gram stain for detection of group B streptococcus in high-risk antepartum patients 965
Craig V. Towers, MD, Thomas J. Garite, MD, Wendy W. Friedman, MT(ASCP), Richard A. Pircon, MD, and Michael P. Nageotte, MD
Long Beach and Irvine, California

An evaluation of a new enzyme-linked immunosorbent assay test combined with the Gram stain for rapid detection of group B streptococcus is presented.

Amniotic fluid glucose concentration: A rapid and simple method for the detection of intraamniotic infection 968
Roberto Romero, MD, Carlos Jimenez, MD, Ajay K. Lohda, MD, Jose Nores, MD, Shuichi Hanaoka, MD, Cecilia Avila, MD, Robert Callahan, BS, Moshe Mazor, MD, John C. Hobbins, MD, and Michael P. Diamond, MD
New Haven, Connecticut

Amniotic fluid glucose determination is a rapid and simple test for the detection of intraamniotic infection.

Contents

False-negative syphilis screening: The prozone phenomenon, nonimmune hydrops, and diagnosis of syphilis during pregnancy 975
Kathleen Berkowitz, MD, Laxmi Baxi, MD, and Harold E. Fox, MD
New York, New York

Patients with false-negative syphilis serology results caused by the prozone phenomenon whose infants had congenital syphilis are described and recommendations for accurate diagnosis made.

Intrapartum hepatitis B screening in a low-risk population 978
J. M. Ernest, MD, Laurence B. Givner, MD, and Robert Pool, MD
Winston-Salem, North Carolina

Intrapartum hepatitis B surface antigen screening in a low-risk population allows timely administration of hepatitis B immune globulin to the newborn.

Risk factors associated with the increasing prevalence of pneumonia during pregnancy 981
K. Berkowitz, MD, and A. LaSala, MD
New York, New York

The rising prevalence and severity of community-acquired antepartum pneumonia are correlated with maternal drug use and human immunodeficiency virus status.

Ultrasonographic fetal weight estimation by an integrated computer-assisted system: Can each laboratory improve its accuracy? 986
Howard O. Thompson, MD, Cynthia Casaceli, BS, and James R. Woods, Jr., MD
Rochester, New York

Estimated fetal weights from 1684 cases were used to evaluate the accuracy, determine institutional weight estimation equation, and establish an optimal examination-to-birth interval.

Ultrasonographic assessment of intestinal damage in fetuses with gastroschisis: Is it of clinical value? 995
Roger R. Lenke, MD, Wayne H. Persutte, BS, RDMS, and Joanne Nemes, RNC
Toledo, Ohio

In those cases of gastroschisis detected prenatally, in utero measurements of fetal bowel seem to be ineffective as indicators for delivery intervention.

Lack of specific placental abnormality associated with cocaine use 998
William M. Gilbert, MD, Christopher M. Lafferty, MD, Kurt Benirschke, MD, and Robert Resnik, MD
San Diego, California

Detailed gross and microscopic examination of placentas from 13 pregnancies complicated by cocaine abuse revealed no specific pathologic abnormalities.

TRANSACTIONS OF THE FIFTY-SECOND ANNUAL MEETING OF THE SOUTH ATLANTIC ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Retrospection and prospection 1000
Allan G. W. McLeod, MD
Miami, Florida

Invasive carcinoma of the vulva 1007
Denis Cavanagh, MD, James V. Fiorica, MD, Mitchel S. Hoffman, MD, William S. Roberts, MD, S. C. Peter Bryson, MD, James P. LaPolla, MD, and Desmond P. J. Barton, MD
Tampa, Florida

This is an analysis of 34 years' experience with the surgical management of 415 patients with invasive carcinoma of the vulva, with review of the survival patterns and morbidity.

Bacterial vaginosis and trichomoniasis vaginitis are risk factors for cuff cellulitis after abdominal hysterectomy 1016
David E. Soper, MD, Richard C. Bump, MD, and W. Glenn Hurt, MD
Richmond, Virginia

Patients with bacterial vaginosis and trichomoniasis vaginitis are at increased risk of the development of cuff cellulitis after abdominal hysterectomy.

Cases with ruptured membranes that "reseal" 1024
John W. C. Johnson, MD, Robert S. Egerman, MD, and Jacquelyn Moorhead, MStat
Gainesville, Florida

Patients with preterm prepartal rupture of the membranes that subsequently cease leaking amniotic fluid continue their pregnancies and have improved obstetric outcomes.

The use of serial CA 125 concentrations to monitor endometriosis in infertile women 1032
Donald E. Pittaway, MD, PhD
Winston-Salem, North Carolina

In women with endometriosis and elevated CA 125 concentrations, serial determinations had prognostic value with regard to pregnancy rates and correlated with the clinical course of the disease.

Multiple endocrine adenomatosis type I in pregnancy 1037
Alexander R. Smythe II, MD, Kay F. McFarland, MD, Mohammed Yousufuddin, MD, and William D. Meredith, MD
Columbia, South Carolina

A patient with multiple endocrine adenomatosis type I in pregnancy is presented; diagnosis of insulinoma was confirmed by arteriography and symptoms resolved after delivery and partial pancreatectomy.

Contents

The diagnostic values of concurrent nonstress testing, amniotic fluid measurement, and Doppler velocimetry in screening a general high-risk population 1040

Lawrence D. Devoe, MD, Paula Gardner, RN, Cheryl Dear, RN, and Ramon A. Castillo, MD
Augusta, Georgia

One thousand high-risk obstetric paitents were screened with a combination of nonstress testing, amniotic fluid volume assessment, and Doppler velocimetry; the nonstress test had the highest sensitivity for all risk conditions, whereas test combinations offered the lowest predictive errors for all conditions examined.

Eclampsia. VI. Maternal-perinatal outcome in 254 consecutive cases 1049

Baha M. Sibai, MD
Memphis, Tennessee

There was one maternal death, but morbidity was frequent among 254 patients with eclampsia managed at one perinatal center.

Experience with the EndoPap device for the cytologic detection of uterine cancer and its precursors: A comparison of the EndoPap with fractional curettage or hysterectomy 1055

James P. LaPolla, MD, Santo Nicosia, MD, Charles McCurdy, MD, Curtis Songster, MD, Eugene Ruffolo, MD, William S. Roberts, MD, Mitchel S. Hoffman, MD, James V. Fiorica, MD, and Denis Cavanagh, MD
Tampa and St. Petersburg, Florida

EndoPap uterine cytologic sampling was highly sensitive for the detection of uterine malignancy and atypical endometrial hyperplasia.

Diagnosis and management of prenatally detected myelomeningocele: A preliminary report 1061

William A. Hogge, MD, Jeffrey S. Dungan, MD, Mark P. Brooks, MD, Susan A. Dilks, MD, Patricia L. Abbitt, MD, Siva Thiagarajah, MBBS, and James E. Ferguson, MD
Charlottesville, Virginia

A coordinated management approach to the fetus with myelomeningocele appears to enhance the potential for a favorable outcome.

Outpatient obstetric management of women with type I diabetes 1065

F. John Bourgeois, MD, and Jeanne Duffer, MSN
Charlottesville, Virginia

Perinatal mortality and morbidity were not different in type I diabetic women managed as outpatients when compared with similarly complicated diabetic women managed as inpatients.

Effectiveness of 1% lidocaine dorsal penile nerve block in infant circumcision 1074

Robert M. Arnett, MD, J. Stephen Jones, MD, and Edgar O. Horger III, MD
Charleston, South Carolina

The use of 0.4 ml of 1% lidocaine in dorsal penile nerve blocks decreases stress seen in infant circumcision.

Reducing cesarean sections at a teaching hospital 1081
Luis Sanchez-Ramos, MD, Andrew M. Kaunitz, MD, Herbert B. Peterson, MD, Beverly Martinez-Schnell, PhD, and Robert J. Thompson, MD
Jacksonville, Florida, and Atlanta, Georgia

At a teaching hospital serving indigent patients, the cesarean section rate was reduced from 28 to 11 per 100 deliveries without compromising neonatal outcome.

Calcium every day
Aerobics every wee
Bone loss every yea

She needs PREMARIN to help prevent further bone loss

Calcium[1] and exercise are not enough to prevent post-menopausal osteoporosis, since estrogen deficiency is the primary cause.[2] PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.[3]

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.[4]

PREMARIN®

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women. Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogen-dependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

See important information on adjacent page.

For moderate-to-severe vasomotor symptoms and for osteoporosis

PREMARIN®
(conjugated estrogens tablets)

0.3 mg 0.625 mg 0.9 mg 1.25 mg 2.5 mg

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY. Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.
There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose.

Blood pressure should be monitored with estrogen use, especially if high doses are used.

Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risk, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one without another physical examination being performed. Conditions influenced by fluid retention, such as asl epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may de manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens shou used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases assoc with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-proc combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinepl induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormon measured by T_4 levels determined by column or by radioimmunoassay. Free T_3 resin uptake is decre reflecting the elevated TBG; free T_4 concentration is unaltered.
3. Impaired glucose tolerance.
4. Reduced response to metyrapone test.
5. Reduced serum folate concentration.

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and syn estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See **CONTRAINDICATI** and Boxed Warning.

NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy; changes in vaginal ble pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of u fibromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of br nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hirsutism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, n depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porp edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe vasomotor symptoms, atr vaginitis, or atropnic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest that will control symptoms should be chosen and medication should be discontinued as promptly as pos Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or medication should be made at three- to six-month intervals.
2. *Given cyclically:* Hypoestrogenism. Osteoporosis.

Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 followed by 10 day rest period. If bleeding does not occur by the end of this period, the same dosage sched repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or down according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effi control.

Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week of

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinu promptly as possible.

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream shou monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the ev persistent or recurring abnormal vaginal bleeding.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the

Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

nly your important observations; do not compare your bservations with those of others. Such comparisons and omments are reserved for the Comment section.

In the *Comment* section state the importance and ignificance of your findings but do not repeat the details iven in the Results section. Limit your opinions to those trictly indicated by the facts in your report. Compare your ndings with those of others. No new data should be resented in this section.

Acknowledgments. Acknowledge only persons who have iade substantive contributions to the study.

References. A reasonable number are allowed, except in ase reports and brief communications (limited to 2) and in ianuscripts for the Current Development section (for 'hich there is no limit). Number references consecutively in ie order in which they are mentioned in the text. Use the ɔrmat of the "Uniform Requirements for Manuscripts ubmitted to Biomedical Journals" (Vancouver style) (Ann ntern Med 1988;108:258-65). Journal titles should con-ɔrm to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if ssential, may be used but not as numbered references. If iey are used, they are to be referred to, within parenthe-es, at the appropriate location in the text. If used, the uthor(s) must obtain written and signed permission for ieir use from the individual being quoted. This signed ermission must accompany the manuscript when it is ubmitted to the Editor. Abstracts are not acceptable as umbered references.

Illustrations and tables. Illustrations and tables should ipplement, not duplicate, the text; presentation of data in ither one or the other will suffice.

A reasonable number of halftone and line illustrations ill be reproduced without charge, but special arrange-ients must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in

sequence after the references. Titles should be included in the legend, *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words [excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"]. The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

–The original and two copies of the manuscript are submitted.
–The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
–Three sets of unmounted glossy photographic prints are submitted, properly numbered and labeled on the back of each print.
–Three sets of computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
–Human experimentation has been approved by the local institution as stated in the Methods section.
–Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
–The covering letter with essential information is with the manuscript.
–All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
–All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
–Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
–Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

–In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

–In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

–Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title
—Author(s) name(s) and highest academic degree(s)
—City(ies), state(s), and country other than U.S. in which the study was conducted are given
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated
—Acknowledgment of financial support is cited
—Name, address, and business and home telephone numbers of author to whom requests for reprints are to be sent
—Reprints will not be available. This has been stated on the title page
—Since the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, and business and home telephone numbers have been added
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a caption and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in sequence in the text.

Figures

—Are numbered in Arabic numerals and are cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Abstracts, personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted and the signed approval is enclosed.

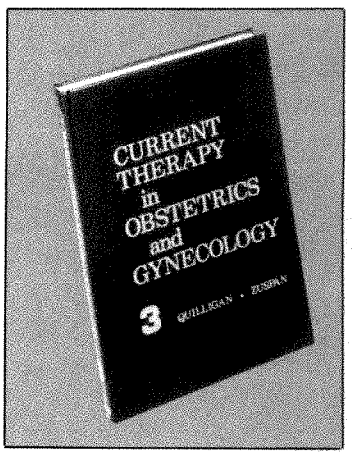
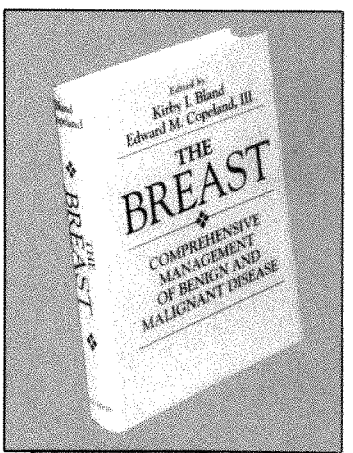
NEW AND ACCLAIMED TEXTS HELP YOU PROVIDE *COMPLETE* OB/GYN CARE!



Harrison, Golbus & Filly
THE UNBORN PATIENT: Prenatal Diagnosis and Treatment, 2nd Edition

New Edition! The pioneers who have brought hope to families of fetuses with diaphragmatic hernias now bring you the latest edition of their flagship reference. You'll see how to diagnose the spectrum of disorders suffered by your fetal patients . . . and how to correct them.
Edited by **Michael R. Harrison, MD, FACS, FAAP,** Prof. of Surg. and Ped., Co-Dir., Fetal Treatment Program, Chief, Div. of Ped. Surg., Univ. of Cal., San Francisco, San Francisco, CA; **Mitchell S. Golbus, MD, FACOG,** Prof. of Obstetrics, Gynecology and Reproductive Sci., and Ped., Co-Dir., Fetal Treatment Program, Dir., Reproductive Genetics Unit, Univ. of Cal., San Francisco, San Francisco, CA; and **Roy A. Filly, MD, FAIUM,** Prof. of Radiology and of Obstetrics, Gynecology, and Reproductive Sci., Co-Dir., Fetal Treatment Program, Chief, Sec. of Diagnostic Ultrasound, Univ. of Cal., San Francisco, San Francisco, CA. Sept. 1990. Over 670 pp. Over 695 ills. (4 in color) $150.00. **Order #W4538-0.**

*From review of a previous edition.

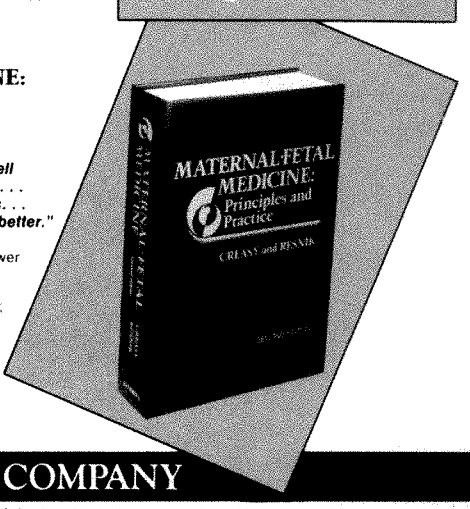


Csonka & Oates
SEXUALLY TRANSMITTED DISEASES: A Textbook of Genito-Urinary Medicine *(A Bailliere Tindall book)*

NEW! This clinical resource offers you a wealth of current, practical information on important viral diseases — such as AIDS, herpes, and genital warts — and on more easily treated STDs like syphilis and gonorrhea.
By **G. Csonka, MD,** and **J.K. Oates, MD,** both of the Dept. of Genito-Urinary Med., The Westminster Hosp., London. Sept. 1990. Over 600 pp. Over 290 ills. (32 in color) $95.00. **Order #B1258-0.**

Quilligan & Zuspan
CURRENT THERAPY IN OBSTETRICS AND GYNECOLOGY 3

NEW! ***"A unique approach . . . provides an instant consultation with an expert for almost any problem. This chance to obtain a superb second opinion is a great aid to the clinician."*** *(The New England Journal of Medicine*)*
Edited by **Edward J. Quilligan, MD,** Prof. of Obstetrics and Gynecology, The Univ. of Cal., Irvine, Irvine, CA; and **Frederick P. Zuspan, MD,** Richard L. Meiling Prof., Dept. of Obstetrics and Gynecology, The Ohio Univ. Sch. of Med., Columbus, OH. June 1990. 454 pp. 92 tables, 45 figs. $45.00. **Order #W3069-3.**



Bland & Copeland
THE BREAST: Comprehensive Management of Benign and Malignant Disease

The most comprehensive book on breast disease guides you through surgical procedures and concepts, reconstructive procedures, therapeutics, and rehabilitation. You'll appreciate the multidisciplinary approach — with each chapter written by an acknowledged authority.
By **Kirby I. Bland, MD,** Prof. and Assoc. Chair., Dept. of Surg., Univ. of Fl., Gainesville, FL; and **Edward M. Copeland, III, MD,** Prof. and Chair., Dept. of Surg., Univ. of Fl., Gainesville, FL. Oct. 1990. Over 1280 pp. Over 775 ills. $150.00. **Order #W2234-8.**

Creasy & Resnik
MATERNAL-FETAL MEDICINE: Principles and Practice, 2nd Edition

"A standard reference textbook . . . well balanced . . . particularly thorough. . . addresses all the important clinical issues. . . An excellent book that has become even better." *(The New England Journal of Medicine)*
By **Robert K. Creasy, MD,** Emma Sue Hightower Prof. and Chair., Dept. of Obstetrics, Gynecology and Reproductive Sci., Univ. of Texas Med. Sch. at Houston, Houston, Texas; Chief, Obstetrics and Gynecology, Hermann Hosp., Houston, TX; and **Robert Resnik, MD,** Prof. and Chair. of Reproductive Med., Univ. of Cal., San Diego Sch. of Med., San Diego, CA; Chief of Obstetrics and Gynecology, Univ. of Cal. San Diego Med. Ctr., San Diego, CA. 1989. 1236 pp. 764 ills. $99.00. **Order #W2304-2.**

Tri-Levlen® means a low incidence of breakthrough bleeding/spotting*†

Multicenter study demonstrates significantly less breakthrough bleeding/spotting through the first six cycles[1]

n = number of women with a bleeding event occurring during a cycle.

TRI-LEVLEN®

Levonorgestrel and ethinyl estradiol tablets Triphasic regimen

may mean a lot to a woman

* Incidence defined as percentage of women with a bleeding event occurring at least once during a pill cycle.

Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

† Defined as intermenstrual bleeding.

Ortho-Novum® is a registered trademark of Ortho Pharmaceutical Corp.

BERLEX Dedicated to innovation in OB/GYN medicine

TRI-LEVLEN® 28 Levonorgestrel and ethinyl estradiol
TRI-LEVLEN® 21 tablets–Triphasic regimen

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma.* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring.* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects.* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure.* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in use and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive method. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factor VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert. 60611-1 5/86

Metabolism of cocaine by human placentas: Implications for fetal exposure

Daniel A. Roe, BS, Bertis B. Little, PhD, Roger E. Bawdon, PhD, and Larry C. Gilstrap III, MD

Dallas, Texas

To assess placental metabolism of cocaine, placentas were obtained at the time of delivery and the microsomes were extracted by ultracentrifugation within 2 hours. Placental microsomes were cultured with cocaine at physiologic plasma concentrations similar to those of cocaine users (0.75 μg/ml). Two control groups were established. In the first group an anticholinesterase was added to the culture to suppress enzyme activity, and in the second cocaine was cultured alone without placental microsomes to obtain baseline spontaneous conversion of the drug. The results indicate that cocaine is biotransformed by the human placenta, presumably by cholinesterase activity. This suggests that the placenta may provide a moderate degree of protection from cocaine-induced morbidity, such as abruptio placentae and fetal growth retardation, by converting cocaine into less active metabolites. These results also have pharmacogenetic implications because cholinesterase activity varies among individuals. Hence placentas that cannot transform the drug may place the conceptus at greater risk of developmental abnormalities. (AM J OBSTET GYNECOL 1990;163:715-8.)

Key words: Placenta, metabolism, cocaine, microsome, cholinesterase

In this country one in 10 fetuses is exposed to cocaine via maternal abuse.[1] This exposure may result in or contribute to a myriad of medical problems, including increased frequency of congenital anomalies,[2-5] fetal growth retardation,[6, 7] perinatal cerebral hemorrhage or infarction,[8] neonatal withdrawal symptoms,[7, 9] abruptio placentae,[10] premature birth,[5, 7, 11] and stillbirth.[6]

An important defense against physiologically active substances such as cocaine is enzymatic transformation of them in the serum and in select organs. The placenta, which filters the entire maternal-fetal circulation and contains considerable amounts of smooth endoplasmic reticulum, is a strategic metabolic interface between mother and child and may serve a protective role in maternal cocaine abuse. Although researchers have confirmed placental biodegradation of amphetamine, meperidine, paraaminobenzoic acid, and pentobarbital,[12] previous investigation of placental metabolism of cocaine was confounded by use of frozen placental tissue.[13]

The purpose of this study was to assess the ability of the human placenta to transform maternal serum cocaine into its metabolites. This information is essential to better understand the fetal risk of cocaine-induced morbidity and mortality.

Material and methods

A dozen placentas from routine pregnancies were collected at the labor and delivery unit of Parkland

Memorial Hospital in Dallas from term mothers who had uncomplicated vaginal or cesarean deliveries. The placentas were placed on ice and transported to the laboratory within 30 minutes of delivery.

Placentas of women with clinically recognized infectious disease or a history of drug abuse were excluded from the study. Inquiries into maternal drug use were made throughout the prenatal course and reported in the patient's chart; consistent negative responses by the mother were considered reliable for this study.

The experiment was designed according to a previously published protocol.[12] In the laboratory the placentas were manually compressed and rinsed in a large volume of cold saline solution. Approximately 25 gm of tissue was resected from randomly selected areas of each placenta, and each piece of tissue was rinsed again with cold saline solution. This rendered the tissue essentially free of blood. The tissue was then minced and homogenized with a Tekmar Tissumizer SDT-1810 in two volumes of cold 0.1 M potassium phosphate buffer, pH 7.4.

The resultant 75 ml of homogenate was transported on ice to a Sorvall RCFC centrifuge, divided equally into two tubes, and centrifuged at 9000 *g* for 15 minutes at 4° C. The supernatant resulting from one tube was refrigerated at 4° C for 1 hour. The supernatant from the second tube was subjected to centrifugation at 104,000 *g* for 1 hour at 4° C with a Beckman L8-70M ultracentrifuge. The latter method produced a pellet of concentrated microsomal proteins. The pellet was collected and reconstituted in phosphate buffer.

Assay solutions were prepared by combining 4 ml of enzyme preparation with 0.75 μg/ml cocaine and phosphate buffer, resulting in a final volume of 5 ml. This concentration of cocaine has been documented to be achievable through typical intranasal administration.[14] In accordance with published protocol,[12] the majority of the assay solutions were prepared with the low-speed (9000 *g*) centrifugate; the microsomal fraction produced by ultracentrifugation was verified to be the source of the activity for each placenta.

Two control groups were established. Anticholinesterase (1,5-bis(4-allyldimethylammoniumphenyl)-pentan-3-one dibromide (obtained from Sigma Chemical Co.) was added to a group of assay solutions (3 mg/5 ml) to selectively inhibit placental cholinesterases. In addition, cocaine (0.75 μg/ ml) was added to phosphate buffer in the absence of placental supernatant to establish baseline spontaneous conversion of the drug.

Time elapsed from removal of tissue from circulation (i.e., delivery) to initiation of incubation averaged 3½ hours. Each 5 ml aliquot was incubated at 37° C in a shaking water bath for a total time of 135 minutes, with a 1 ml sample taken at initial composition and then every 45 minutes. These intervals were based on data that the half-life of cocaine in the human is approximately 45 minutes.[14]

At each interval the 1 ml sample was immediately frozen at −70° C. Subsequently the samples were thawed and cocaine and its metabolites were isolated according to an alkaline drug extraction protocol developed in our laboratory. Relative concentrations of cocaine were obtained from the injection of 3 μl of the extract into the capillary column of a Hewlett Packard 5890A gas chromatograph. Our standard curve for determining absolute cocaine concentrations used lidocaine as an internal standard. Lidocaine was a reliable standard; it was not used systemically as part of the anesthetic procedures during cesarean delivery.

Linear regression of six different lidocaine-cocaine concentrations plus a zero point produced a standard curve with an R^2 value of 0.96 ($R = 0.98$). Newman-Keuls multiple comparisons were used to analyze the difference in cocaine concentrations between groups over time. Tests were performed on The University of Texas Southwestern Medical Center's VAX8800 computer with UTSTAT software.

Results

Our results demonstrate a 20% decrease in the concentration of cocaine over the period of the experiment; the majority of the decline occurred in the first 45-minute interval (Fig. 1). This is a statistically significant ($p < 0.01$) decrease as indicated by the fact that the ending point is ≥7 SEs below the starting point (Table I). The spontaneous conversion of cocaine (cocaine alone without microsomes) was minimal over the time periods studied. Similarly, the concentration of cocaine did not decrease with the inhibiting addition of the anticholinesterase; the beginning and ending values vary by <1 SE.

Comment

Cocaine is sympathomimetic; it inhibits the reuptake of norepinephrine at adrenergic nerve endings. Cocaine exerts its maternal-fetal physiologic effects by its action on the uteroplacental vasculature and myometrium. This tonic sympathetic stimulation results in acute maternal hypertension, which may lead to abruptio placentae.[10] β-Agonism of the myometrium results in increased uterine contractility and enhanced risk of premature rupture of membranes and preterm labor.[15] Uteroplacental insufficiency resulting from vasoconstriction of the uterine arteries has been correlated with reduced birthweight (<2500 gm), fetal growth retardation (<10th percentile), and fetal intolerance to labor.[11] Cocaine also may induce embryofetal systemic vasoconstriction, resulting in the documented incidence of cardiovascular,[5] genitourinary,[2, 3] gastrointes-

tinal and musculoskeletal anomalies,[4] as well as perinatal cerebrovascular accidents.[8] Finally, cocaine has an anorectic effect,[16] and its use is associated with an increased incidence of sexually transmitted diseases.[17]

In vivo cocaine is transformed into four metabolites: norcocaine, benzoylecgonine, ecgonine methyl ester, and ecgonine. Each is derived from a separate process. Norcocaine arises from the action of an *n*-demethylase present in adult human liver, but this pathway is not significant in human physiology. Benzoylecgonine appears spontaneously; it is not enzyme dependent. Ecgonine methyl ester results from the action of cholinesterases. Ecgonine is the sequela of both benzoylecgonine and ecgonine methyl ester and may arise from enzymatic hydrolysis.[14]

With consideration of these metabolic pathways the 20% decrease in cocaine concentration observed in this study can be attributed to the action of placental cholinesterase for two reasons: Cocaine levels did not decline when enzymatic inhibition was achieved with anticholinesterase and the decrease in cocaine concentration cannot be ascribed to any nonenzymatic reaction (such as that yielding benzoylecgonine) because the group with cocaine without microsomes exhibited no change.

Thus the biotransformation of cocaine by placental

cholinesterases yields metabolites that are more polar and less pharmacologically active than cocaine. Therefore, this conversion may offer a degree of protection against adverse maternal-fetal effects. This enzymatic activity, present in the term placenta, has not been documented in the first-trimester placenta; therefore the role of the early placenta in protection from cocaine-induced congenital anomalies during the critical developmental period remains to be elucidated.

These results also have pharmacogenetic implications because (1) genetic polymorphisms for cholinesterase exist, creating a broad spectrum of enzymatic potential,[18] (2) cholinesterase deficiency or low activity has been associated with enhanced cocaine toxicity in the adult,[19] and (3) the frequency of low cholinesterase activity or inactivity is 1% to 13% in North America, according to ethnic origin.[18] Hence placentas that cannot transform the drug may place the conceptus at greater risk of suffering cocaine-induced morbidity or mortality.

Survival rates of monoamniotic twins do not decrease after 30 weeks' gestation

Stephen R. Carr, MD, Michael P. Aronson, MD, and Donald R. Coustan, MD
Providence, Rhode Island

A search of pathology records from the years 1967 to 1988 at Women and Infants' Hospital of Rhode Island (138,232 live births) revealed 24 sets of histologically confirmed monoamniotic twins. All records were available for review. Among the 17 sets of monoamniotic twins that reached 30 weeks' gestation with at least one twin still alive, there were no further fetal deaths. The risks of early delivery in these pregnancies appear to outweigh the risk of fetal death as a result of monoamniotic status alone. These data do not show an advantage to early delivery. (Am J Obstet Gynecol 1990;163:719-22.)

Key words: Monoamniotic twins, life table analysis, mortality

Monoamniotic twinning is a rare event widely recognized to have increased antenatal and perinatal morbidity and mortality.[1-9] The striking increases in morbidity and mortality rates have focused attention on these pregnancies well in excess of their incidence.

Although the exact incidence of monoamniotic twins is difficult to ascertain, the incidence in various studies ranged from 1 : 1650[10] to 1 : 93,734[7] live births. Because of an impression of increasing morbidity and mortality rates in monoamniotic twin pregnancies with advancing gestational age, delivery early in the third trimester has been advocated.[11] As a result of the rarity of monoamniotic twinning, publications in which their outcome is examined have consisted almost exclusively of case reports or collections of case reports, limiting the conclusions that may be drawn concerning optimal management, and in particular, the timing of delivery.

Methods

Prompted by the admission for preterm labor of a woman carrying monoamniotic twins, a thorough search of records at Women and Infants' Hospital of Rhode Island from the years 1967 to 1988 was carried out. Twenty-four sets of histologically confirmed monoamniotic twins were identified, of which all records were available for review. During the 21-year interval there were 138,232 live births at the hospital. Each of the records was searched for selected prenatal and outcome variables. Death of a twin or twins was considered to be a result of monoamniotic status only if intertwined umbilical cords or vascular anastamoses with evidence of twin-to-twin transfusion were described by the delivering obstetrician or pathologist. All intrauterine deaths in this series met these criteria. Life table analysis was used with survival of at least one twin, and then survival of both twins, as the indicators of a favorable outcome to determine the cumulative proportional fetal survival rates of those monoamniotic twins identified and to determine whether and when during the course of the pregnancy these rates stabilized.

Results

The significant finding was that there were no further fetal deaths after 30 weeks' gestation in our study sample. Of the 24 sets of monoamniotic twins known to be alive before 18 weeks' gestation, 15 sets were alive/alive at 30 weeks, one set was delivered and survived, two sets were alive/dead, and six sets were dead/dead. Of those 17 sets of twins with at least one twin alive at 30 weeks' gestation, all 17 showed no further fetal death up to the time of delivery (Table I). The life table analysis reveals that the cumulative proportional fetal survival rate with double twin survival stabilized at 0.79 at 30 weeks' estimated gestational age. When survival of at least one twin was used as the indicator of a favorable outcome, the cumulative proportional fetal survival rate stabilized at 0.81 at 30 weeks. The cumulative risk trend for survival of at least one twin is represented graphically in Fig. 1.

Perinatal survival of both twins occurred in 46% of cases, and perinatal survival of at least one twin occurred in 63% of cases. The average gestational age at delivery in those cases with double survival was 36.5 weeks (SD, ±3.38; range, 29 to 42 weeks), and in those cases with at least one survivor was 36.3 weeks (SD, ±3.59; range, 29 to 42 weeks). Antenatal diagnosis of

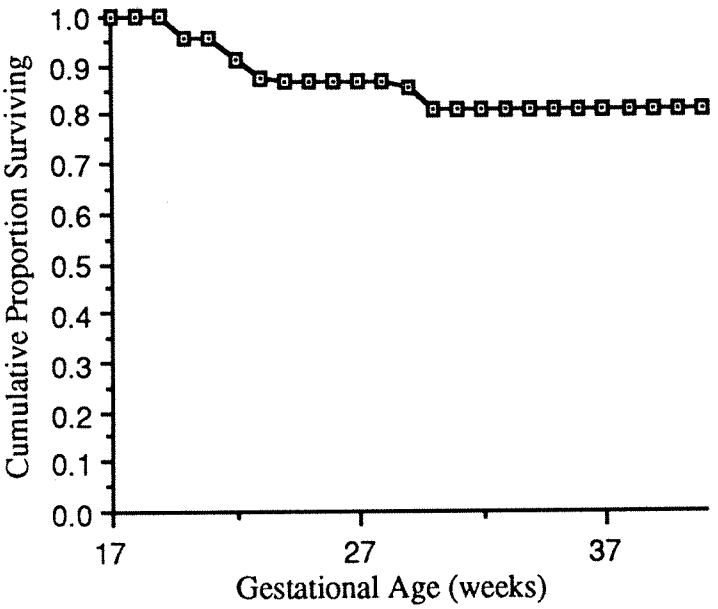

Fig. 1. Cumulative proportional fetal survival rate as function of gestational age with at least one survivor in 24 sets of monoamniotic twins.

Table I. Fetal deaths among monoamniotic twins

<18 weeks	*30 weeks*	*Delivery*
A/A = 24	A/A = 16 A/D = 1 D/D = 6	A/A = 16 A/D = 1 D/D = 6

A/A, Both twins alive; *A/D*, one twin alive and one dead; *D/D*, both twins dead.

monoamniotic twins was made in only 21% of cases, and the diagnosis of twins made in just 29% of cases. Even in the 1980 to 1988 epoch, when the diagnosis of twins was more likely to have been made antenatally, only 44% of cases were identified. Hydramnios was noted as a complicating factor in 25% of cases, and vascular anastamoses between twins were identified in 46% of cases. Vaginal delivery was accomplished in 75% of individual neonates, and in 48% of live-born infants. The sex ratio of our sets of twins was 1.18 (13 sets males, 11 sets females), higher than figures cited.[12] There was no case in which one fetus was delivered vaginally and the other by cesarean section.

The power of life table analysis lies in its ability to determine the extent of ongoing risk to the population under study and to identify the time of minimal risk. Knowing the proportion of the population of interest that survives each given interval, a cumulative proportional fetal survival rate can be calculated as the product of the proportions surviving each interval up to the time of interest. If we are considering delivering a pregnancy early to avoid fetal death, then we need to examine the consequences of that decision. Goldenberg et al.[13] identified week-specific cumulative and incremental survival rates of singleton neonates as a function of gestational age. One minus the week-specific neonatal survival rate yields a week-specific neonatal death rate, and this number can be compared with week-specific fetal death rates attributed to monoamniotic status to arrive at decisions concerning timing of delivery. The probability of two independent events occurring in association is the product of the individual probabilities of those two events. If we assume that the neonatal deaths of both monoamniotic twins (if delivered) are independent events, the week-specific neonatal death rates are the square of the week-specific neonatal death rates for singleton pregnancies as determined by Goldenberg et al.[13] These squared death rate data are presented graphically in Fig. 2. Recall that when in utero survival of at least one twin in each set is used as the marker of a favorable outcome, the cumulative proportional fetal survival rate stabilized at 0.81 at 30 weeks' gestation. This means that a set of monoamniotic twins identified at <18 weeks' gestation with both twins alive can be given an 81% chance of survival of at least one twin to 30 weeks. Conversely, there is a 19% cumulative proportional death rate. This death rate is greatest early in that 18-week to 30-week gestational age interval, and decreases as survival of one or both twins is documented closer and closer to 30 weeks. This decrease in the cumulative proportional fetal death rate is presented in Fig. 3 along with the curve generated from the squared week-specific neonatal death rates derived from the data of Goldenberg et al.[13] At no time does the week-specific fetal death rate because of monoamnionicity alone exceed the week-specific neonatal death rate because of prematurity. It appears from this data set that the risk of fetal death as a result of mono-

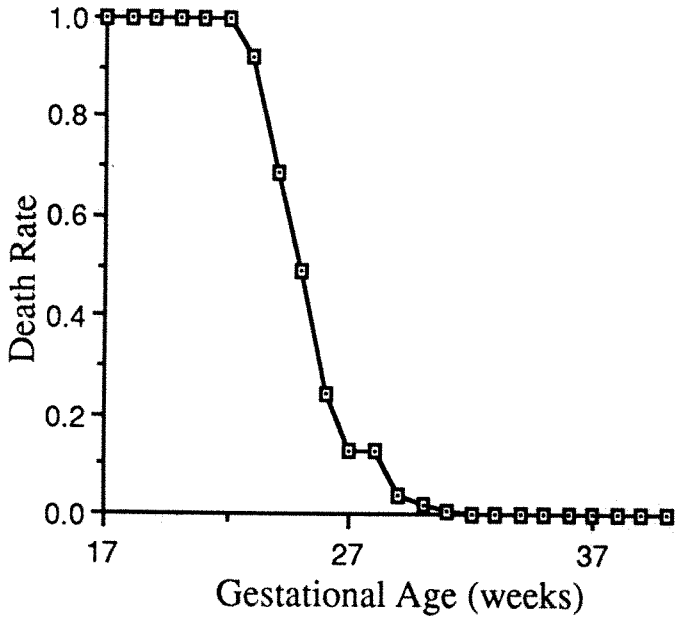

Fig. 2. Neonatal death rates in monoamniotic twins as function of gestational age, assuming that individual deaths are independent events. Data derived from Goldenberg et al. 1984.[13] See Results section for explanation.

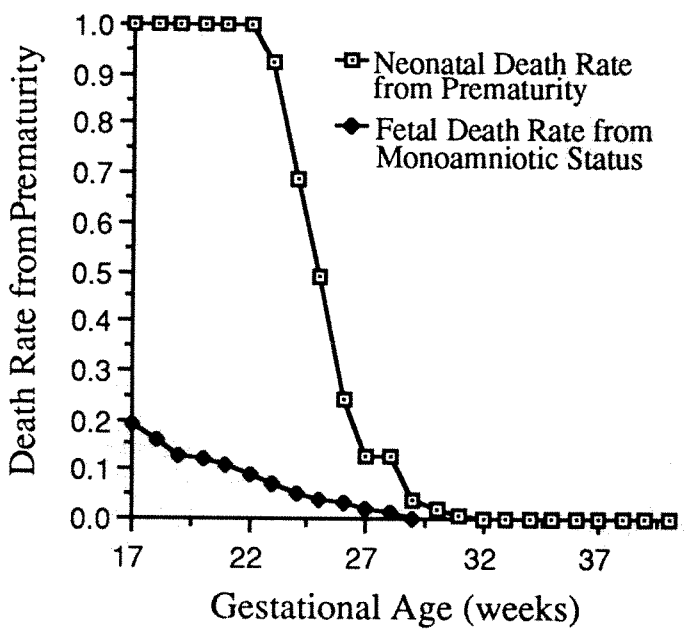

Fig. 3. Week-specific death rates from prematurity and from monoamniotic status alone. Neonatal death rates are derived from data in Goldenberg et al. 1984.[13] Fetal death rates as a result of monoamnionicity are derived from life table analysis as explained in text.

amnionicity is counter-balanced by the improvement in neonatal survival as pregnancy progresses.

Comment

Twins have higher morbidity and mortality rates than do singleton pregnancies,[14-17] and in monoamniotic twins in particular these measures are even higher.[1-10] The particularly high morbidity and mortality rates seen in monoamniotic twins have been attributed to premature delivery, vascular anastamoses between the twins, congenital anomalies, and to intertwining and knotting of the umbilical cords,[1-10] with cord accidents apparently contributing the largest portion. Quigley[1] reported a mortality rate of 68% in monoamniotic twins, and stated that double survival of monoamniotic twins was a rare event. He attributed the

very high mortality rate to intertwining and knotting of the umbilical cords. Twenty-four years later, Salerno[5] reported a double survival rate of 63%, and found that the high mortality rate was primarily a result of cord entanglements and prematurity. The 46% double perinatal survival rate found among our cases agrees well with the 46% survival rate determined by Raphael[8] from a literature review for the time period 1935 to 1961, encompassing 74 sets of monoamniotic twins.

On the basis of small data sets, some authors have advocated delivery of monoamniotic twin pregnancies immediately on demonstration of fetal pulmonic maturity, whenever in the pregnancy that may occur,[2] whereas others have recommended delivery at or about 32 weeks' gestation because of what was thought to be increasing risk as the monoamniotic pregnancy progressed.[11] However, not all authors have agreed with the idea that risks to monoamniotic fetuses necessarily increase as gestational age advances past the early third trimester.[18] These opinions have been expressed with relatively little objective data for support. Whereas our sample size of 24 may appear to be a relatively small number on which to base decisions concerning timing of delivery, no larger population-based data sets are currently available. Our incidence of 1 in 5760 live births agrees well with figures quoted in the literature and suggests that ours is a complete sample.

Our analysis and conclusions may be criticized on the basis of two arguments. The first is the arbitrary decision to use the survival of at least one twin as the marker of a favorable outcome in these pregnancies. When double survival is used as the favorable event marker, the cumulative proportional fetal survival rate is 0.79 at 30 weeks' gestation, only slightly lower than if survival of at least one twin is used. The use of 0.79 as the cumulative proportional fetal survival rate generates cumulative proportional fetal death rates that are slightly higher than those derived above, but they never exceed the week-specific death rate as a result of prematurity alone.

The second argument is with the assumption that the neonatal deaths of a set of monoamniotic twins are independent events. The increased risk of death to the surviving twin in a set of monoamniotic twins with single fetal death is well recognized and is reinforced by our finding that in the eight sets of our twins that had some fetal mortality, it was double mortality in six sets. If we assume that the neonatal deaths of both monoamniotic twins (if delivered) are dependent events, the week-specific neonatal death rate is the sum of the individual week-specific death rates for each of the two twins. This would serve to increase the separation between the week-specific death rate as a result of prematurity and the week-specific death rate as a result of monoamnionicity. Again, we arrive at the same conclusion.

Our data do not reveal an advantage to delivery of monoamniotic twin pregnancies at 32 weeks' gestation. Whereas our sample size of 24 cannot eliminate the possibility of fetal death after 30 weeks' gestation in monoamniotic twin pregnancies, it suggests that these events will be infrequent. Whether demonstration of fetal pulmonic maturity will be an important factor in determining the timing of delivery in these pregnancies remains to be elucidated.

We gratefully acknowledge the assistance of Donald Singer, MD, in obtaining pathology reports on the pregnancies reported here.

Ultrasonographic evaluation of uteroplacental blood flow patterns of abnormally located and adherent placentas

Glenford P. Guy, MD, David B. Peisner, MD, and Ilan E. Timor-Tritsch, MD
New York, New York

Transvaginal ultrasonography was used to evaluate antepartum bleeding in a group of 76 patients at varying gestational ages with suspected placenta previa. The clinical outcome of 16 patients with persistent placenta previa was documented. Nine of the 16 patients had placental lacunar blood flow. Two of the nine patients were lost to follow-up. At cesarean section the seven patients with lacunar flow had a higher incidence of blood loss, transfusion requirements, abnormally implanted placenta, and cesarean hysterectomy than the six patients in whom no lacunar flow patterns were seen ($p = 0.002$). The finding of these flow patterns with abnormally located placentas suggests the anticipation of significant blood loss and probable extension of operative procedures to stop the blood loss. (AM J OBSTET GYNECOL 1990;163:723-7.)

Key words: Placenta previa, placenta accreta, pregnancy, transvaginal ultrasonography, placental blood flow, cesarean hysterectomy

The safe use of transvaginal ultrasonography in patients suspected of placenta previa has been reported.[1, 2] Vaginal transducers enabled accurate imaging of the relationship between the placenta and the internal cervical os. Visual observation of blood flow within the placenta and the related cervical and pelvic blood vessels were also possible. The presence of unusually intense and pulsatile blood flow patterns within several sonolucent structures that appeared to be placental lakes drew our attention to these patients. The purpose of this article is to describe the outcomes in patients with placenta previa and lacunar blood flow.

Material and methods

Seventy-six women with antepartum bleeding and suspected placenta previa were evaluated. A 6.5 MHz mechanical sector scanner (Elscint Ltd., Haifa) at varying frame rates was used. The ultrasonographic texture of these placentas was documented. If lacunar flow was seen within the placenta near or overlapping the internal os the scanning rate was increased for better imaging and a videotape recording of the examination was made. Five of eight patients with lacunar flow were identified both retrospectively by reviewing videotapes and then collecting clinical data. Three of the eight cases were followed up prospectively.

To be confirmed as a lacunar flow pattern, the following placental characteristics were required: thickness > 1 cm with multiple sonolucencies (blood lakes), lakes occupying almost the entire thickness of the placenta from the basal plate to the chorionic plate, and visibility of blood flow (pulsatile and laminar) within these lacunae at high scanning frame rates. The borders between the placental and the myometrial or cervical tissues may not be distinguishable. Dilated vascular structures with pulsatile flow may also be visualized within the nonplacental tissue.

The following clinical outcome data were reviewed retrospectively: previous cesarean section, previous placenta previa, mode of delivery, amount of described blood loss, amount of blood replacement, additional operative procedures (ligation of vessels, hysterectomy), and the histologic feature of the placenta and uterus. Statistical analysis was done with Fisher's exact test. The comparison groups used in both p value calculations were patients with or without lacunar blood flow necessitating cesarean hysterectomy (7/14) or cesarean section (7/13). All of the patients' physicians were aware of the diagnosis of abnormally located placenta, if present, and the lacunar flow pattern. However, the clinical significance of the flow pattern was not yet clear during the early part of the series.

Criteria used for the termination of growth retardation were limited to the postpartum definition of Battaglia and Lubchenco.[3] This identified infants <10th percentile of birth weight for given gestational age (< 2500 gm at term).

Results

There was no increased bleeding in the patients examined after transvaginal ultrasonography. At the initial examination no placenta previa was detected in 13

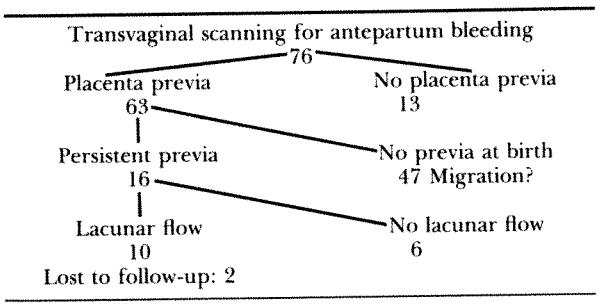

Fig. 1. Patient distribution.

of the 76 patients. Of the remaining 62 patients 16 showed persistent placenta previa. Forty-seven had no placenta previa on subsequent scanning or had vaginal deliveries (Fig. 1). Ten of the 16 patients with persistent placenta previa had lacunar flow patterns. Two of these 10 were lost to follow-up. Seven had homogeneous placentas without the lacunar flow pattern.

The transvaginal ultrasonographic image of a typical patient with a normal homogeneous placenta and a superimposed drawing for orientation is shown in Fig. 2. A typical lacunar structure within an abnormal placenta is shown in Fig. 3.

The outcomes of the eight patients with lacunar flow in the placenta are shown in Table I. Two of the patients with lacunar flow had clinically determined placenta accreta. Patient No. 4 underwent a second laparotomy hours after the cesarean section to control the persistent bleeding. However, a cesarean hysterectomy finally was necessary. Patient No. 2 had a previous placenta previa and six previous cesarean sections. The remaining cases had microscopically determined abnormally implanted placentas. Patient No. 8 refused any further blood transfusion beyond two units against medical advice.

The six patients without flow patterns and homogeneous-appearing persistent placenta previa had cesarean deliveries. None had placenta accreta or a hemorrhagic course necessitating arterial ligation or cesarean hysterectomy.

There were no neonatal or maternal mortalities. The morbidity in all cases emanated from blood loss, operative time, and the impact of transfusion. Patient No. 2 also had disseminated intravascular coagulation. There were two multiple gestations among the patients without lacunar blood flow, and these necessitated preterm deliveries. A total of six preterm deliveries occurred (three from the group with nonflow pattern and three from the lacunar flow group). In cases of term deliveries (> 37 weeks) there were no infants with birth weights < 10th percentile for given gestational age. The average birth weight for the term lacunar flow group (four patients) was 3115 gm (range, 2120 to 3735 gm) and for the term nonlacunar flow group (three patients) 3156 gm (range, 2810 to 3350 gm).

There was a significant risk of hemorrhagic complication necessitating termination by cesarean hysterectomy among the patients with lacunar flow patterns. When compared with blood loss in patients with lacunar flow, the mean estimated blood loss among the patients with nonlacunar blood flow was 967 ml (range, 700 to 1500 ml). The mean estimated blood loss among the patients with lacunar flow was 2900 ml (range, 1000 to 4000 ml). Patients with lacunar flow also had an increased risk of abnormally implanted placenta when compared with patients without lacunar blood flow ($p = 0.002$).

Comment

Transvaginal ultrasonography is highly suited for evaluation of placenta previa because of the direct visualization of the critical tissue areas that the probe provides. In the cases of abnormally implanted placentas, the cervix and the lower uterine segment can be accurately evaluated. The lacunar pattern described here was associated with a high operative risk for increased bleeding in six of the seven patients. This consistency prompted us to study the underlying pathology.

The microhemodynamics of blood flow in the intervillous space is of interest because of the flow patterns we observed. The understanding of the development of normal uteroplacental circulation, and the interaction of the invading trophoblast has come from many sources. Questions remain with regard to the earliest contact of maternal blood with the intervillous spaces.[4] However, the dynamics of uteroplacental blood flow has been demonstrated in primates by Ramsey and Donner[5] with subsequent extrapolations to human placentas. Extravillous trophoblast first migrate from the cytotrophoblastic shell[6] and subsequently from the anchoring villi[7] to penetrate the decidua. The trophoblasts then travel to the inner layer of the myometrium to a depth of a few millimeters.[8, 9] This interstitial migration is thought to prepare the spiral arteries for conversion by the endovascular migratory trophoblast to physiologic (dilated) conduits.[10] This endovascular cytotrophoblastic migration becomes part of the spiral arterial wall to produce the physiologic conversion (dilatation) of these arteries alone.[11] The conversion results in increased volume of blood to the intervillous space and a reduced pulse pressure.[12] Ramsey's classic model of "no preformed channels," and "reduced pulse pressure" were not patterns seen in these placentae. Poiseuillian perfusion, and not the Darcian model of percolation advanced by Schmid-Schonbeim,[13] was seen in these lacunar regions. We observed a pulsatile type of perfusion and turbulent flow in areas where the placenta appeared to have lost parenchyma. The sonolucencies in these areas imparted a "Swiss cheese" pattern

of dilated lacunae to the normally homogeneous placenta. If percolation of maternal blood among the villi is to enhance gas exchange (respiration),[13] then these areas with loss of villi and perfusion flow may have less adequate function. They are virtual respirational dead spaces and act only as conduits. The high hemorrhagic potential given the blood flow observed within them can be visualized. However, it is of interest that growth retardation was not seen in these fetuses.

A strong association between the abnormally adherent placenta and the lacunar flow was found. The histopathogenesis of abnormally adherent placenta results from the reduction of decidua in the placental bed and the trophoblastic invasion of the myometrium.[14, 15] There is an increased incidence of abnormally adherent placentas in the lower uterine and cervical canal where poor decidual reaction occurs.[16] The histopathologic role of previous cesarean section is less clear but its persistent association with abnormally adherent placentas is well documented.[15-19] All these risk factors were found in our patients. Khong and Robertson[20] reviewed 20 cases of placenta accreta to assess the histopathologic correlates of trophoblastic migration and the development of vasculature in these specimens. The most unusual finding was that the physiologic vessel dilation that normally is limited to the spiral arteries was also seen in the higher pressure, larger arteries of the radial, arcuate, and parametrial systems. Many spiral arteries also were found to lack physiologic vessel dilation. Khong and Robertson hypothesized that this pathologic recruitment of the arterial system was to compensate for the frequent findings of inadequate uteroplacental circulation, especially in placenta "previa creta" specimens. The spiral arteries normally conduct blood to the intervillous space under low pressure. The impact on the placental parenchyma of this compensatory neovascularization is unknown. Observations suggest that the blood flow is transmitted from arteries of greater pulse pressure; the impact of this flow will be the focus of our future reports. Our current findings of wide channels, with perfusion flow and pulsatile activity within the placental parenchyma, appear to contradict

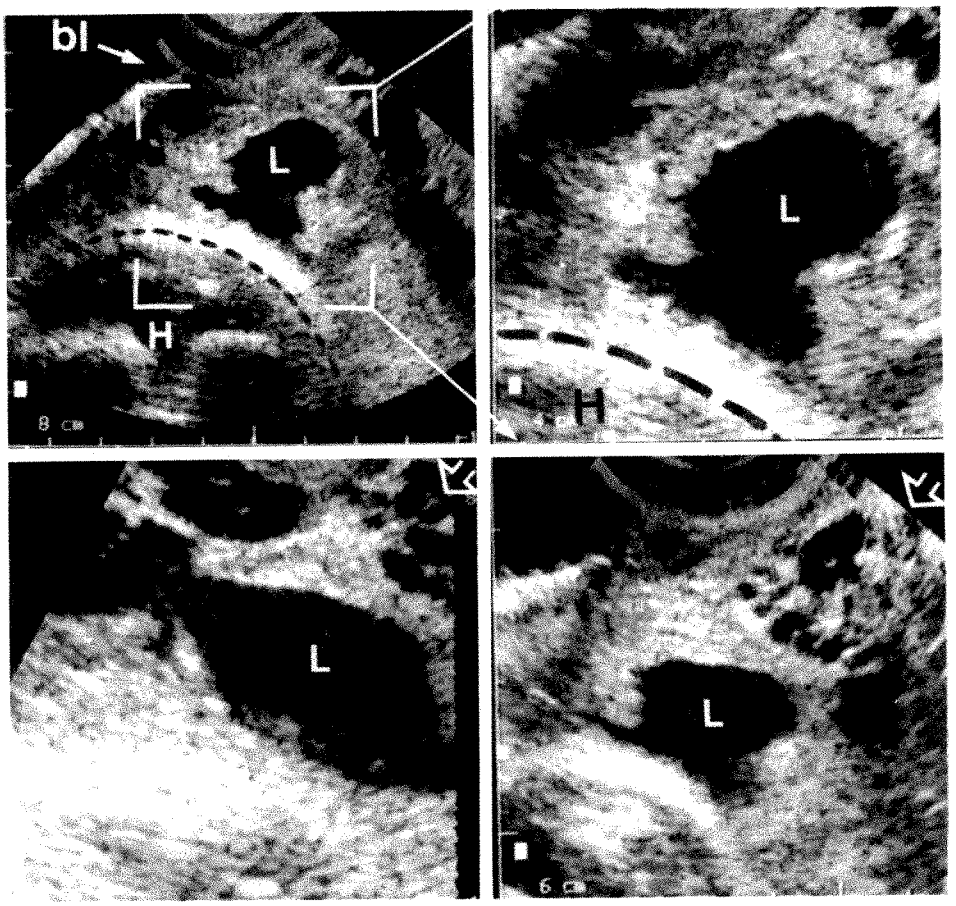

Fig. 3. Transvaginal ultrasonographic sagittal views demonstrate typical "Swiss cheese" pattern of lucencies in abnormally adherent placenta with lacunar flow. *Bl*, Bladder; *L*, lacunae; *H*, head; external os, open arrows.

previously published models pertinent to the microhemodynamics of the intervillous space.

Our observations suggest transmission of high pulse-pressure blood flow from the deep arterial system. The imaged channels and lakes may represent areas of villous attenuation through either infarct, fibrosis, or abnormal nidation. These formations are analogous to the "jet lesions" observed in ventricular septal defects. These lesions are tissue alterations resulting from long exposure to pulsatile blood flow[21] and may have been formed concurrently or subsequently to the aforementioned neovascularization. The result is carved-out areas within the placenta, which appear as sonolucencies, and serve only as blood flow conduits that will bleed extensively at delivery. An ultrasonographic observation of "hypervascularization" was reported by Mendonca[2] in six cases of abnormally adherent placenta. Although their instruments did not have flow monitoring capabilities, we believe the findings are similar to ours.

We conclude that if this pattern of lacunar blood flow is seen, it may predict abnormally adherent placenta (7/8, 87.5% of the lacunar flow group); large blood losses (mean estimated blood loss of 967 ml in a non-lacunar flow group 2814 ml in the lacunar blood flow group); the need for extensive operative therapy (7/8, 87.5% of the lacunar flow group). We believe the following interventions are reasonable in cases with placental and lacunar blood flow patterns: (1) Inform the patient of possible morbidity and blood loss and the possible need for transfusions, operative therapy, or both. (2) Notify the anesthesiologist of the risk of blood loss and other operative interventions. (3) Obtain prior consent for uterine or hypogastric artery ligation or cesarean hysterectomy.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Transplacental transfer of zidovudine in the near-term pregnant baboon

Gary D. V. Hankins, MD,[a] Curtis L. Lowery, Jr., MD,[c] Richard T. Scott, MD,[a] W. Robert Morrow, MD,[a] K. D. Carey, DVM, PhD,[b] M. Michelle Leland, DVM,[b] and Edward V. Colvin, MD[c]

Lackland Air Force Base and San Antonio, Texas, and Birmingham, Alabama

Approximately one third of infants born to human immunodeficiency virus type 1 seropositive mothers have evidence of infection or of acquired immunodeficiency syndrome by the age of 18 months. One fifth of infected infants also have died by age 18 months. This prevalence, combined with the demonstration that zidovudine (formerly azidothymidine) can decrease mortality and the frequency of opportunistic infections in patients with acquired immunodeficiency syndrome or acquired immunodeficiency syndrome—related complex, may lead to increasing use of azidothymidine in pregnancy despite a paucity of information regarding its pharmacokinetics. To further investigate the distribution of azidothymidine and its inactive metabolite 5′-glucuronide azidothymidine in the mother, fetus, and amniotic fluid, 12 near-term pregnant baboons were given oral azidothymidine (21 mg/kg/day in four divided doses every 6 hours, equivalent to the usual nonpregnant human dose of 1500 mg/day). Specimens of maternal blood, fetal arterial blood obtained by percutaneous umbilical cord blood sampling, and amniotic fluid were obtained after from one to 17 doses of azidothymidine. Azidothymidine levels were measured by radioimmunoassay with the INCSTAR commercial radioimmunoassay kit and using *Escherichia coli* β-glucuronidase for determination of 5′-glucuronide azidothymidine levels. Paired analyses revealed significant concentration gradients between amniotic fluid, fetal serum, and maternal serum for both azidothymidine ($p < 0.019$) and 5′-glucuronide azidothymidine ($p < 0.002$). The amniotic fluid 5′-glucuronide azidothymidine level increased with increasing doses of azidothymidine despite the fact that the maternal azidothymidine and 5′-glucuronide azidothymidine concentrations were unchanged. This accumulation of amniotic fluid 5′-glucuronide azidothymidine may provide a functional drug reservoir and contribute to the higher fetal concentrations of the medication and its metabolite. Alternatively, the higher fetal levels may represent slower clearance in the fetus than in the mother. Further studies appear warranted with respect to possible adverse fetal effects, especially bone marrow suppression with prolonged and chronic exposure to azidothymidine. (Am J Obstet Gynecol 1990;163:728-32.)

Key words: Azidothymidine, acquired immunodeficiency syndrome, placental transfer

Few disease states have garnered national and international attention and action as quickly as the acquired immunodeficiency syndrome (AIDS). Demand for responsiveness by the scientific and medical community has been intense and action has been prompt. The Food and Drug Administration approved clinical testing of zidovudine (azidothymidine) within 5 days of receipt of its sponsor's application. The review and approval of the zidovudine New Drug Application required only 107 days and clinical studies of only 22 months.[1] Optimism over the demonstration that azidothymidine administration could decrease mortality and the frequency of opportunistic infections in a selected group of subjects with AIDS or AIDS-related complex[2] has resulted in ongoing phase 1 clinical trials of zidovudine in pregnancy. Notwithstanding, published data on azidothymidine in pregnancy, especially in the fetus, are limited to a single study involving one pregnant macaque monkey.[3] In an acute preparation involving intravenous administration of zidovudine (44.1 μg/kg/min) for 3½ hours before cesarean birth, azidothymidine was demonstrated to cross the placenta with a ratio of the steady-state concentration of the drug in fetus/mother of 0.74. To more closely approximate the usual therapy used in actual clinical practice, we administered the drug per os to 12 pregnant baboons, in the third trimester of pregnancy. Because the drug is metabolized in the liver by attachment of glucuronic acid in the 5′ position with subsequent renal excretion of both the free and conjugated drug, the ability of the fetus to metabolize the drug might be impaired by delayed maturation of the glucuronide enzyme system.

6/6/22358

Indeed, in nonpregnant adults with concurrent acetaminophen and azidothymidine treatment, a higher frequency of hematologic complications have been reported and attributed to increased azidothymidine toxicity as a result of competitive inhibition of hepatic metabolism by the glucuronide system.[4] Accordingly, information on the degree to which azidothymidine and its metabolite 5′-glucuronide azidothymidine cross the placenta and the levels achieved in the fetus and the amniotic fluid with prolonged long-term therapy is of great importance in assessment of its toxicity and in evaluation of the relative risk/benefit ratio of treatment during pregnancy.

Material and methods

Twelve near-term pregnant baboons *(Papio cyanocephalus)* with a mean gestational age of 169.6 ± 9.0 days were identified for this study after approval by the Animal Use and Care Committee and Investigational Review Committee of the respective institutions. Each animal was studied only once to reduce the effects of anesthesia on the dam and her fetus. The animals had received from one to 17 doses of azidothymidine when studied (Table I). Oral zidovudine was given to the animals in a dose of 100 mg every 6 hours; the powder was mixed with peanut butter or jelly and ingestion by the animals was observed. The dose was selected to approximate that reported by Fischl et al.[2] of 250 mg every 4 hours for a total daily dose of 1500 mg. If the average weight of a pregnant woman is assumed to be 70 kg, this would be equivalent to 21.4 mg/kg/day. Because of variance in the weight of the animals, the actual mean dose was 22.9 ± 2.3 mg/kg/day of azidothymidine (range, 19.9 to 26.5 mg/kg/day) (Table I).

After initial sedation with ketamine hydrochloride all animals were intubated and a surgical level of anesthesia was maintained with a combination of nitrous oxide and halothane. Maternal stability was ensured by continuous monitoring of heart rate and rhythm and of arterial blood pressure via a radial arterial catheter. Assessment of the fetal heart rate was by ultrasonographic visualization. The maternal abdomen was sterilely prepped and draped; amniocentesis and percutaneous umbilical cord sampling were performed under ultrasonographic guidance as previously reported.[5] In each instance the fetal umbilical artery was sampled; visual identification of the umbilical artery was verified by performing a blood gas analysis on the specimen obtained. A 3 ml aliquot of fetal blood and 10 ml of maternal blood were obtained simultaneously. In each instance the amniotic fluid (7 ml) was obtained before the percutaneous umbilical cord blood sampling to avoid contamination with either maternal or fetal blood.

Both maternal and fetal blood were centrifuged and the serum was separated and labeled. The samples were stored at −70° C pending analysis for azidothymidine and 5′-glucuronide azidothymidine levels. Amniotic fluid was frozen without centrifugation; in each instance the fluid was clear and free of contamination with either blood or meconium.

Table I. Number of doses of oral azidothymidine and weight-adjusted daily dosage

Animal No.	*Doses*	*Weight (kg)*	*Dosage (mg/kg/day)*

7	9	16.5	24.2
8	12	16.9	23.7
9	13	15.9	25.2
10	16	20.1	19.9
11	17	19.3	20.7
12	17	16.0	25.0
		17.67 ± 1.7	22.9 ± 2.3

All assays for azidothymidine were performed by the Wellcome Research Laboratories by radioimmunoassay with the INCSTAR commercial radioimmunoassay kit. Each specimen was analyzed both before and after incubation with *Escherichia coli* β-glucuronidase; the initial value represented the unconjugated azidothymidine level and the value after incubation represented the total (conjugated and unconjugated azidothymidine) level. The 5′-glucuronide azidothymidine concentration was obtained by subtracting the initial azidothymidine concentration from that after incubation with the β-glucuronidase.[6]

Statistical methods. Evaluation of the relative concentrations of azidothymidine in maternal serum, fetal serum, and amniotic fluid were compared with paired analyses. Similar comparisons were also done for 5′-glucuronide azidothymidine concentrations. The effect of increasing number of doses of azidothymidine on azidothymidine and 5′-glucuronide azidothymidine concentrations was studied by linear regression analysis of azidothymidine and 5′-glucuronide azidothymidine levels in maternal serum, fetal serum, and amniotic fluid. An alpha error <0.05 was considered statistically significant and corrections for multiple comparisons were used as indicated.

Results

The mean azidothymidine concentration in maternal serum (58.6 ± 62.5 ng/ml), fetal serum (78.4 ± 79 ng/ml), and amniotic fluid (254.4 ± 107.8 ng/ml) is shown in Fig. 1; the concentration progressively increased from mother to fetus to amniotic fluid. Similar gradients were observed with 5′-glucuronide azido-

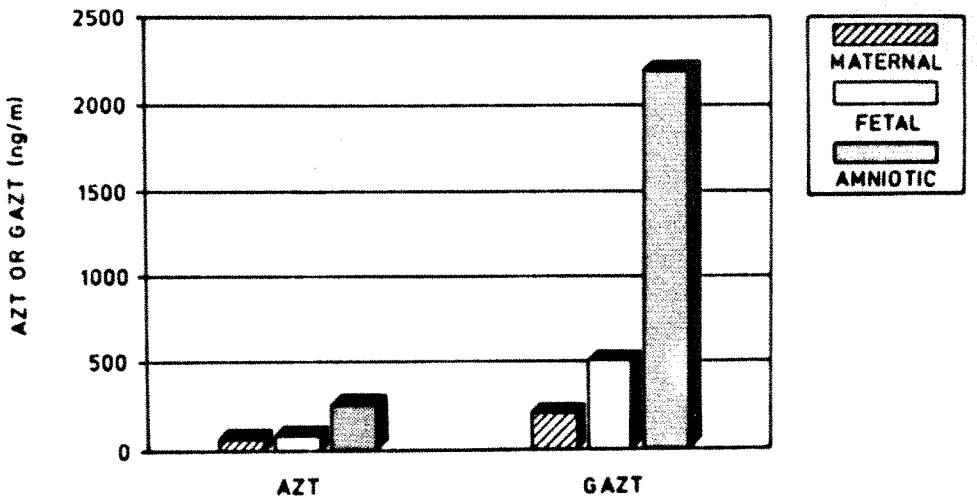

Fig. 1. Azidothymidine and 5′-glucuronide azidothymidine concentrations in maternal serum, fetal serum, and amniotic fluid in near-term pregnant baboons after oral administration of azidothymidine. A clear concentration gradient was present with progressively higher levels being attained in maternal serum, fetal serum, and amniotic fluid ($p < 0.0001$).

thymidine; the maternal serum value was 203.9 ± 189.9 ng/ml, the fetal serum value was 511.8 ± 399.3 ng/ml, and the amniotic fluid value was 2194.1 ± 1208.2 ng/ml. In the evaluation of each individual animal, in only one instance did the maternal azidothymidine level exceed that of the fetus ($p = 0.019$). That particular animal received eight doses of azidothymidine. Amniotic fluid azidothymidine levels exceeded those in maternal serum in all 12 animals ($p < 0.0001$) and exceeded those in the fetus in 11 of 12 animals ($p < 0.0001$). The single exception was an animal that had received only one dose of azidothymidine approximately 3 hours before sampling. In this particular animal the maternal concentration was 144 ng/ml, fetal concentration 163 ng/ml, and maniotic fluid concentration 147 ng/ml. The concentration of azidothymidine in maternal serum, fetal serum, or amniotic fluid showed no apparent relationship to the number of doses received (p = NS), especially within the range of four to 17 doses (Fig. 2).

Similar to the findings with azidothymidine, 5′-glucuronide azidothymidine levels in the fetus exceeded those in the mother in 11 of 12 animals ($p = 0.002$), and amniotic fluid concentrations greatly exceeded those in the maternal serum in all cases ($p < 0.0001$). Amniotic fluid 5′-glucuronide azidothymidine levels exceeded those of the fetus in 11 of 12 animals ($p = 0.0004$); the one exception was the animal that had received only one dose of azidothymidine approximately 3 hours before sampling. In this animal the maternal 5′-glucuronide azidothymidine level was 410 ng/ml, the fetal level was 852 ng/ml, and the amniotic fluid level was 651 ng/ml. There was no detectable change in maternal or fetal circulating concentrations with increasing numbers of doses (p = NS). Significantly, the concentration of 5′-glucuronide azidothymidine in amniotic fluid did show a positive correlation with the number of doses of medication the animals had received before sampling ($p < 0.01$) (Fig. 3).

Comment

The full impact of AIDS on women and children in the United States remains a future, but certain, event. Currently the reported cases of AIDS in children in the United States are <2% of the number in adults,[7] and serologic prevalence of human immunodeficiency virus among childbearing women remains low (2.1/1000).[8] However, this is not universally the case; Ryder et al.[9] reported that 5.8% of pregnant women screened in Zaire were seropositive for human immunodeficiency virus type 1. By 1 year after delivery 21% of infants of seropositive women were dead compared with 3.8% of control infants whose mothers tested negative. Furthermore, 7.9% of the surviving infants had AIDS by the age of 1 year. Similar results have been reported by the French Collaborative Study Group[10] who found that approximately one third of the infants born to seropositive women had evidence of human immunodeficiency virus type 1 infection or of AIDS by age 18 months and that 20% of this group had died.

Treatment of pregnant women with medications potentially toxic to both the woman and her fetus raises several questions: Who is being treated and what are the indications for treatment? Does the fetus possess certain characteristics that may either augment or protect it from drug toxicity? To what extent does the drug

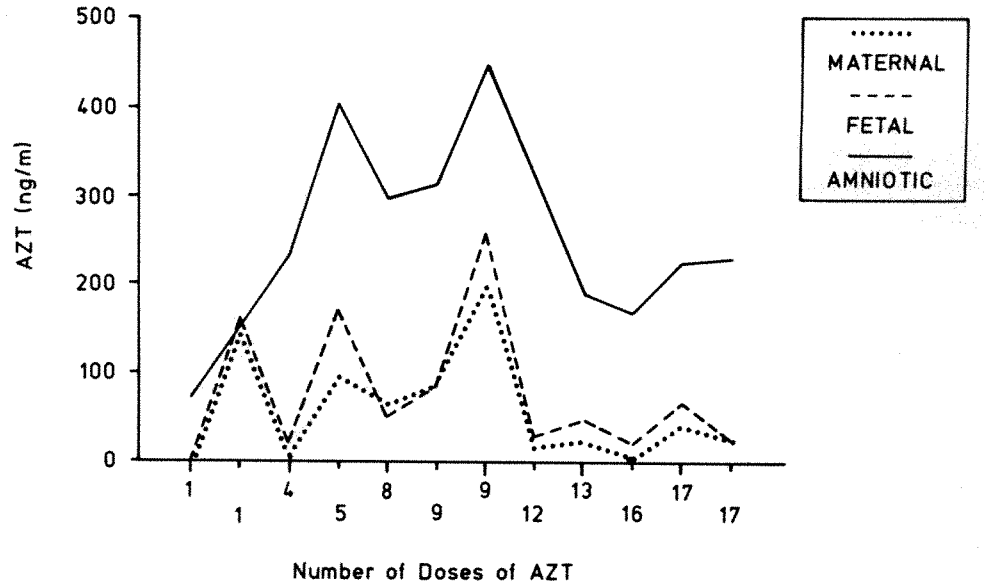

Fig. 2. Azidothymidine concentrations in maternal serum, fetal serum, and amniotic fluid versus the number of doses of azidothymidine. The concentration of azidothymidine was not altered significantly in any of the three compartments with increasing numbers of doses of azidothymidine.

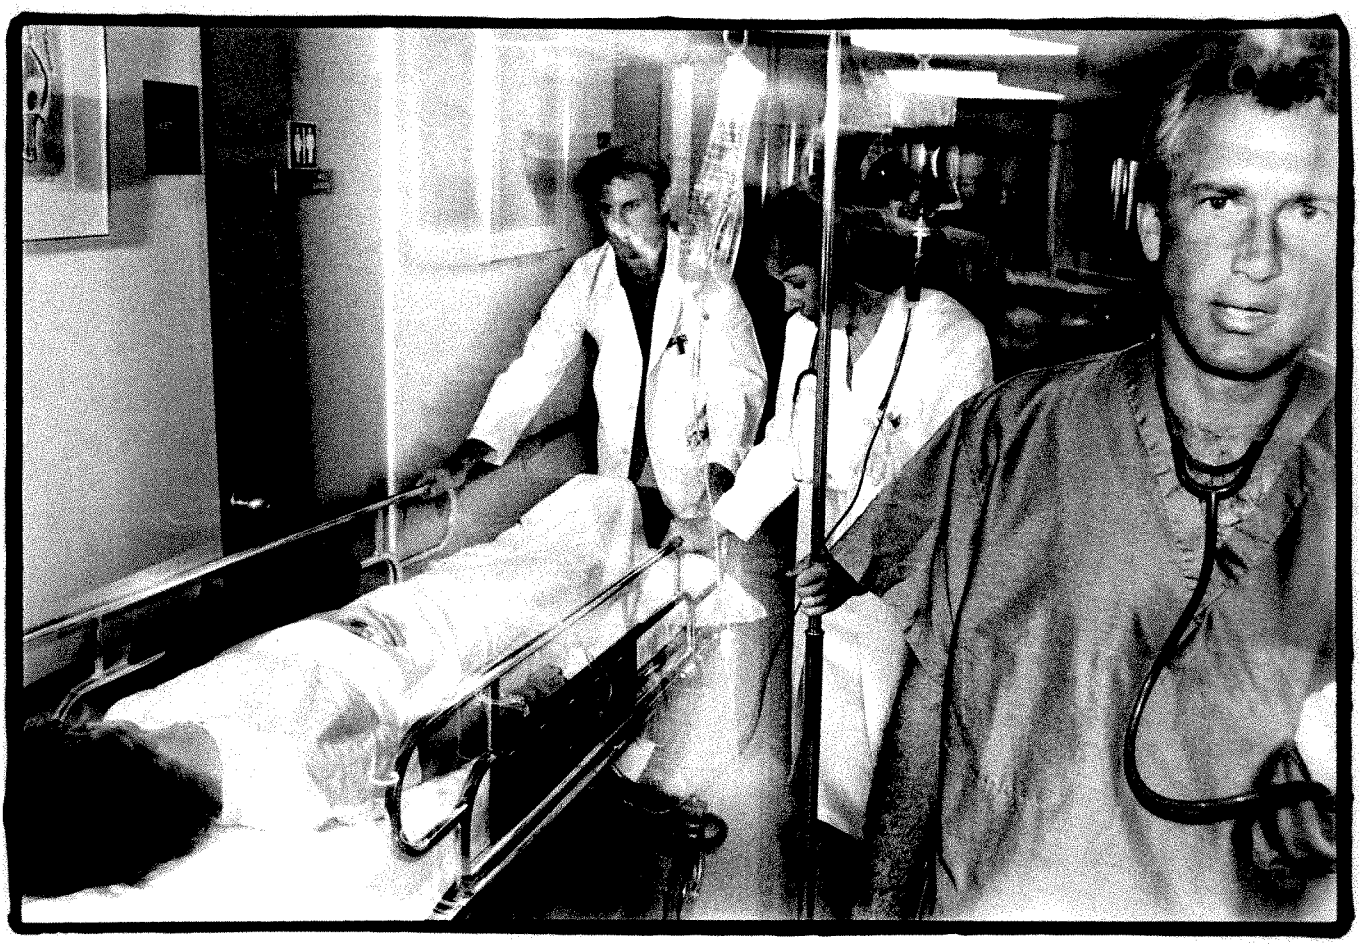
Fig. 3. 5′-Glucuronide azidothymidine concentrations in maternal serum, fetal serum, and amniotic fluid versus the number of doses of azidothymidine. 5′-Glucuronide azidothymidine amniotic fluid concentrations rose with increasing dosages of azidothymidine ($p < 0.01$), whereas maternal and fetal serum levels remained unchanged.

cross the placenta and can maternal drug levels be used to extrapolate to fetal drug levels? In the case of azidothymidine many, if not all, of these questions remain unanswered. Indeed, to date it has not been established whether fetal infection occurs principally in utero by transplacental routes, as occurs with intrauterine rubella, or intrapartum as with the hepatitis B virus.[7]

By use of an animal model with placentation similar to that of humans, we found that the serum concentrations of both azidothymidine and 5′-glucuronide azidothymidine were higher in the fetus than in the mother, irrespective of the number of doses of oral medication the mothers had ingested. After intravenous dosing with azidothymidine in nonpregnant adults, the compound has glucuronic acid attached in the 5′ position in the liver, thereby inactivating a large



percentage of the drug. Further metabolism involves renal clearance; 60% of the drug is excreted in the urine as 5′-glucuronide azidothymidine and 25% as azidothymidine.[11] The increased fetal/maternal ratio of the drug may result from an impaired ability to conjugate the drug by the fetal liver because it is well established that this particular enzyme system does not mature until well after birth. In addition, renal clearance of azidothymidine in the newborn, and by extrapolation of the fetus still in utero, is markedly depressed in relation to that of adults and does not approach the same rate until several days of life.[3] Alternatively, and perhaps synergistically, the high concentrations of both azidothymidine and its metabolite in the amniotic fluid may serve as a source of oral therapy for the fetus via in utero swallowing and absorption. A role for fetal swallowing in the further metabolism of amniotic fluid azidothymidine is supported by the fact that the amniotic fluid azidothymidine concentration did not increase in proportion to the number of doses, whereas concentration of its metabolite 5′-glucuronide azidothymidine did increase (Fig. 3).

With prolonged courses of azidothymidine treatment Richman et al.[4] observed that in 24% of patients anemia developed, defined as a hemoglobin level <7.5 gm/dl, compared with only 4% of patients treated with placebo. Twenty-one percent of azidothymidine recipients and 4% of placebo recipients required multiple red cell transfusions with hematologic toxicity apparently augmented by concurrent use of acetaminophen. Such toxicities may be even more common and severe in the setting of very active bone marrow, such as characterized by both the pregnant woman and her fetus. A parallel between the effects of acetaminophen in the adult and the immature liver of the fetus should be anticipated with respect to more intense hematologic toxicity. Continued usage of these drugs in pregnancy before further detailed animal studies would seem at a minimum to merit intense ultrasonographic surveillance for the potential development of severe fetal anemia and hydrops.

In conclusion, on the basis of data obtained from the pregnant baboon, the fetal levels of azidothymidine will equal or exceed those in the mother. It is anticipated that azidothymidine toxicity in pregnancy, for both mother and fetus, will equal (or exceed) that of nonpregnant patients. We concur that "the priority given studies of possible intrauterine, or neonatal interventions, whether pharmacologic or immunologic, to combat human immunodeficiency virus infection should remain exceedingly high."[7]

"It's still like walking the high wire, but now I have a safety net."

More confidence in presumptive antibiotic therapy. Prescribing UNASYN presumptively is a step you can take with confidence. UNASYN covers gram-positives (even enterococci), prevalent gram-negatives, and anaerobes: The right combination for most patients with common mixed infections.*

And UNASYN minimizes safety concerns with a reliable penicillin-class profile.[1] (However, UNASYN is contraindicated in penicillin-allergic patients.)

Expect strong support from UNASYN in the mixed infections* you face every day.

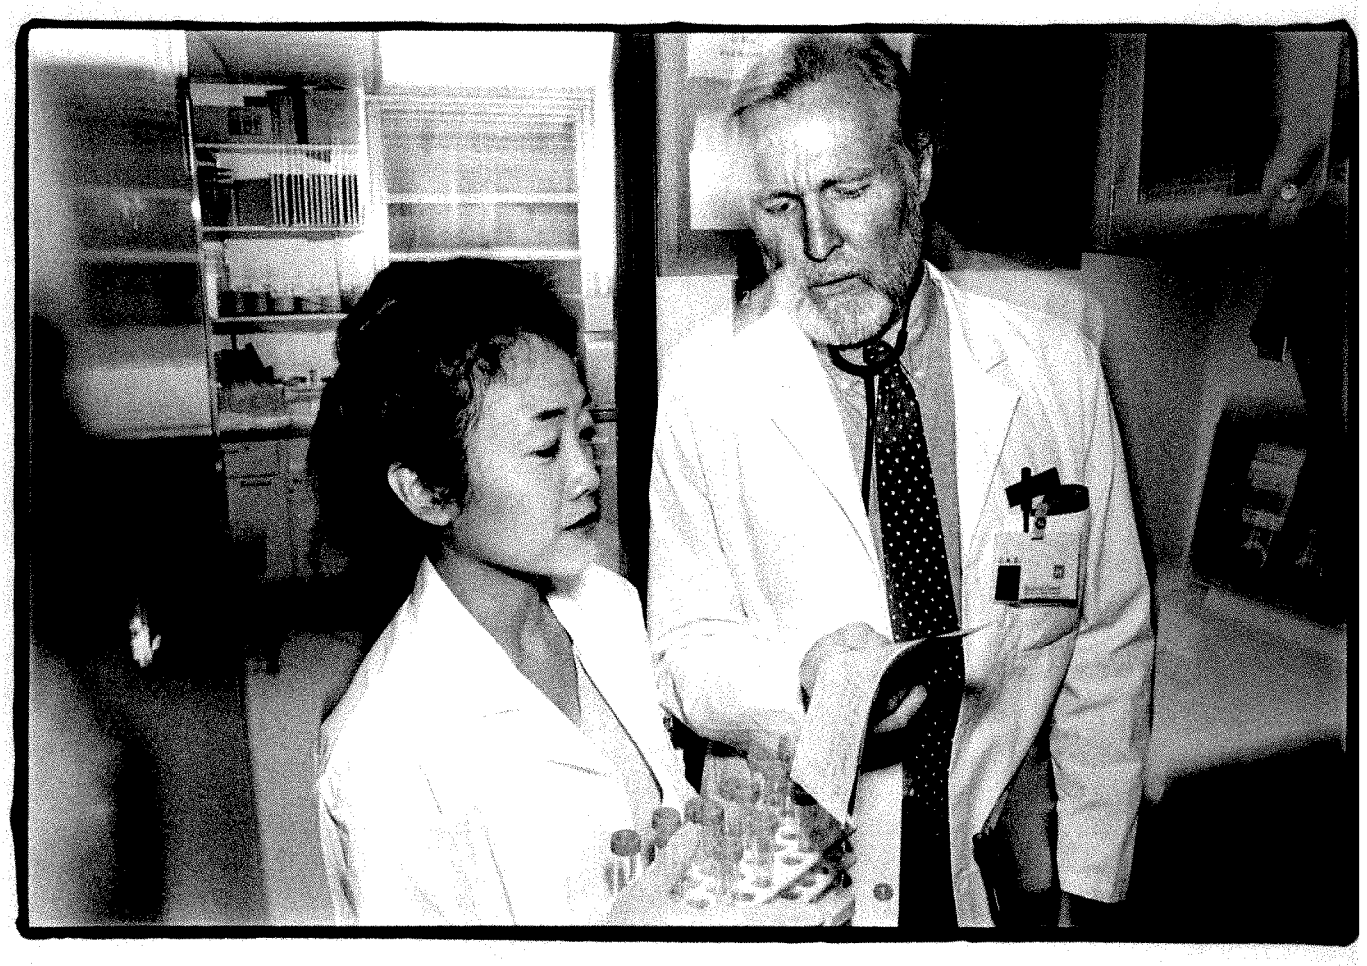
INDICATIONS AND USAGE
UNASYN is indicated for the treatment of infections due to susceptible strains of the designated microorganisms in the conditions listed below:
Skin and Skin Structure Infections caused by beta-lactamase producing strains of *Staphylococcus aureus*, *Escherichia coli*,* *Klebsiella* spp.* (including *K. pneumoniae**), *Proteus mirabilis*,* *Bacteroides fragilis*,* *Enterobacter* spp.,* and *Acinetobacter calcoaceticus*.*
Intra-Abdominal Infections caused by beta-lactamase producing strains of *Escherichia coli*, *Klebsiella* spp. (including *K. pneumoniae**), *Bacteroides* spp. (including *B. fragilis*), and *Enterobacter* spp.*
Gynecological Infections caused by beta-lactamase producing strains of *Escherichia coli*,* and *Bacteroides* spp.* (including *B. fragilis**).
*Efficacy for this organism in this organ system was studied in fewer than 10 infections.
While UNASYN* (ampicillin sodium/sulbactam sodium) is indicated only for the conditions listed above, infections caused by ampicillin-susceptible organisms are also amenable to treatment with UNASYN due to its ampicillin content. Therefore, mixed infections caused by ampicillin-susceptible organisms and beta-lactamase producing organisms susceptible to UNASYN should not require the addition of another antibiotic.

CONTRAINDICATIONS
The use of UNASYN is contraindicated in individuals with a history of hypersensitivity reactions to any of the penicillins.



WARNINGS
SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (ANAPHYLACTIC) REACTIONS HAVE BEEN REPORTED IN PATIENTS ON PENICILLIN THERAPY. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY AND/OR HYPERSENSITIVITY REACTIONS TO MULTIPLE ALLERGENS. THERE HAVE BEEN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE REACTIONS WHEN TREATED WITH CEPHALOSPORINS. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, UNASYN SHOULD BE DISCONTINUED AND THE APPROPRIATE THERAPY INSTITUTED.
SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE, OXYGEN, INTRAVENOUS STEROIDS, AND AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

PRECAUTIONS
General: A high percentage of patients with mononucleosis who receive ampicillin develop a skin rash. Thus, ampicillin class antibiotics should not be administered to patients with mononucleosis. In patients treated with UNASYN, the possibility of superinfections with mycotic or bacterial pathogens should be kept in mind during therapy. If superinfections occur (usually involving *Pseudomonas* or *Candida*), the drug should be discontinued and/or appropriate therapy instituted.
Drug Interactions: Probenecid decreases the renal tubular secretion of ampicillin and sulbactam. Concurrent use of probenecid with UNASYN may result in increased and prolonged blood levels of ampicillin and sulbactam. The concurrent administration of allopurinol and ampicillin increases substantially the incidence of rashes in patients receiving both drugs as compared to patients receiving ampicillin alone. It is not known whether this potentiation of ampicillin rashes is due to allopurinol or the hyperuricemia present in these patients. There are no data with UNASYN and allopurinol administered concurrently. UNASYN and aminoglycosides should not be reconstituted together due to the *in vitro* inactivation of aminoglycosides by the ampicillin component of UNASYN.
Drug/Laboratory Test Interactions: Administration of UNASYN will result in high urine concentrations of ampicillin. High urine concentrations of ampicillin may result in false positive reactions when testing for the presence of glucose in urine using Clinitest™, Benedict's Solution or Fehling's Solution. It is recommended that glucose tests based on enzymatic glucose oxidase reactions (such as Clinistix™ or Testape™) be used. Following administration of ampicillin to pregnant women, a transient decrease in plasma concentration of total conjugated estriol, estriolglucuronide, conjugated estrone, and estradiol has been noted. This effect may also occur with UNASYN.
Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential.
Pregnancy
Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits at doses up to ten (10) times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to UNASYN. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. (See—Drug/Laboratory Test Interactions.)
Labor and Delivery: Studies in guinea pigs have shown that intravenous administration of ampicillin decreased the uterine tone, frequency of contractions, height of contractions, and duration of contractions. However it is not known whether the use of UNASYN in humans during labor or delivery has immediate or delayed adverse effects on the fetus, prolongs the duration of labor, or increases the likelihood that forceps delivery or other obstetrical intervention or resuscitation of the newborn will be necessary.
Nursing Mothers: Low concentrations of ampicillin and sulbactam are excreted in the milk; therefore, caution should be exercised when UNASYN is administered to a nursing woman.
Pediatric Use: The efficacy and safety of UNASYN have not been established in infants and children under the age of 12.

ADVERSE REACTIONS
UNASYN is generally well tolerated. The following adverse reactions have been reported:
Local Adverse Reactions
Pain at IM injection site—16%. Pain at IV injection site—3%.
Thrombophlebitis—3%.
Systemic Adverse Reactions
The most frequently reported adverse reactions were diarrhea in 3% of the patients and rash in less than 2% of the patients.
Additional systemic reactions reported in less than 1% of the patients were: itching, nausea, vomiting, candidiasis, fatigue, malaise, headache, chest pain, flatulence, abdominal distension, glossitis, urine retention, dysuria, edema, facial swelling, erythema, chills, tightness in throat, substernal pain, epistaxis and mucosal bleeding.
Adverse Laboratory Changes
Adverse laboratory changes without regard to drug relationship that were reported during clinical trials were:
Hepatic: Increased AST (SGOT), ALT (SGPT), alkaline phosphatase, and LDH.
Hematologic: Decreased hemoglobin, hematocrit, RBC, WBC, neutrophils, lymphocytes, platelets and increased lymphocytes, monocytes, basophils, eosinophils, and platelets.
Blood Chemistry: Decreased serum albumin and total proteins.
Renal: Increased BUN and creatinine.
Urinalysis: Presence of RBC's and hyaline casts in urine.
The following adverse reactions have been reported with ampicillin-class antibiotics and can also occur with UNASYN:
Gastrointestinal: Gastritis, stomatitis, black "hairy" tongue, enterocolitis and pseudomembranous colitis.
Hypersensitivity Reactions: Urticaria, erythema multiforme, and an occasional case of exfoliative dermatitis have been reported. These reactions may be controlled with antihistamines and, if necessary, systemic corticosteroids. Whenever such reactions occur, the drug should be discontinued unless the opinion of the physician dictates otherwise. Serious and occasional fatal hypersensitivity (anaphylactic) reactions can occur with penicillin (see WARNINGS).
Hematologic: In addition to the adverse laboratory changes listed above for UNASYN, agranulocytosis has been reported during therapy with penicillins. All of these reactions are usually reversible on discontinuation of therapy and are believed to be hypersensitivity phenomena.

"I used to think only <u>two</u> things in life were certain."

Nothing comes closer to 100% activity against anaerobes in vitro. It's a fact. Studies have proved no other antibiotic superior to UNASYN in overall antianaerobic activity.[1-10] Not clindamycin. Not metronidazole. Nothing.

And that's nothing to overlook—given the importance of anaerobes in today's mixed infections.

Though clinical results may not always mirror those obtained in vitro, there's a world of confidence in choosing UNASYN for presumptive therapy of the mixed infections* you see every day.

Healthline

for those who care about health

HEALTHLINE is a monthly, 16-page publication offering up-to-date information on a wide variety of health issues of concern to your patients.

Presented in an attractive two-color format, HEALTHLINE features a concise, easy-to-read style that's ideal for patient education. HEALTHLINE makes excellent waiting room literature.

- Provides the latest health news on disease prevention, nutrition, exercise, mental health, aging, child health, and other topics of interest.
- Alerts your patients to warning signs and symptoms requiring professional attention.
- Presents reliable, *readable* articles written by a national network of doctors, nurses, psychologists, and other health professionals. Edited by Paul M. Insel, PhD, and Walton T. Roth, MD, of the Stanford University School of Medicine.

HEALTHLINE is timely, inviting, enlightening—and *affordable!*

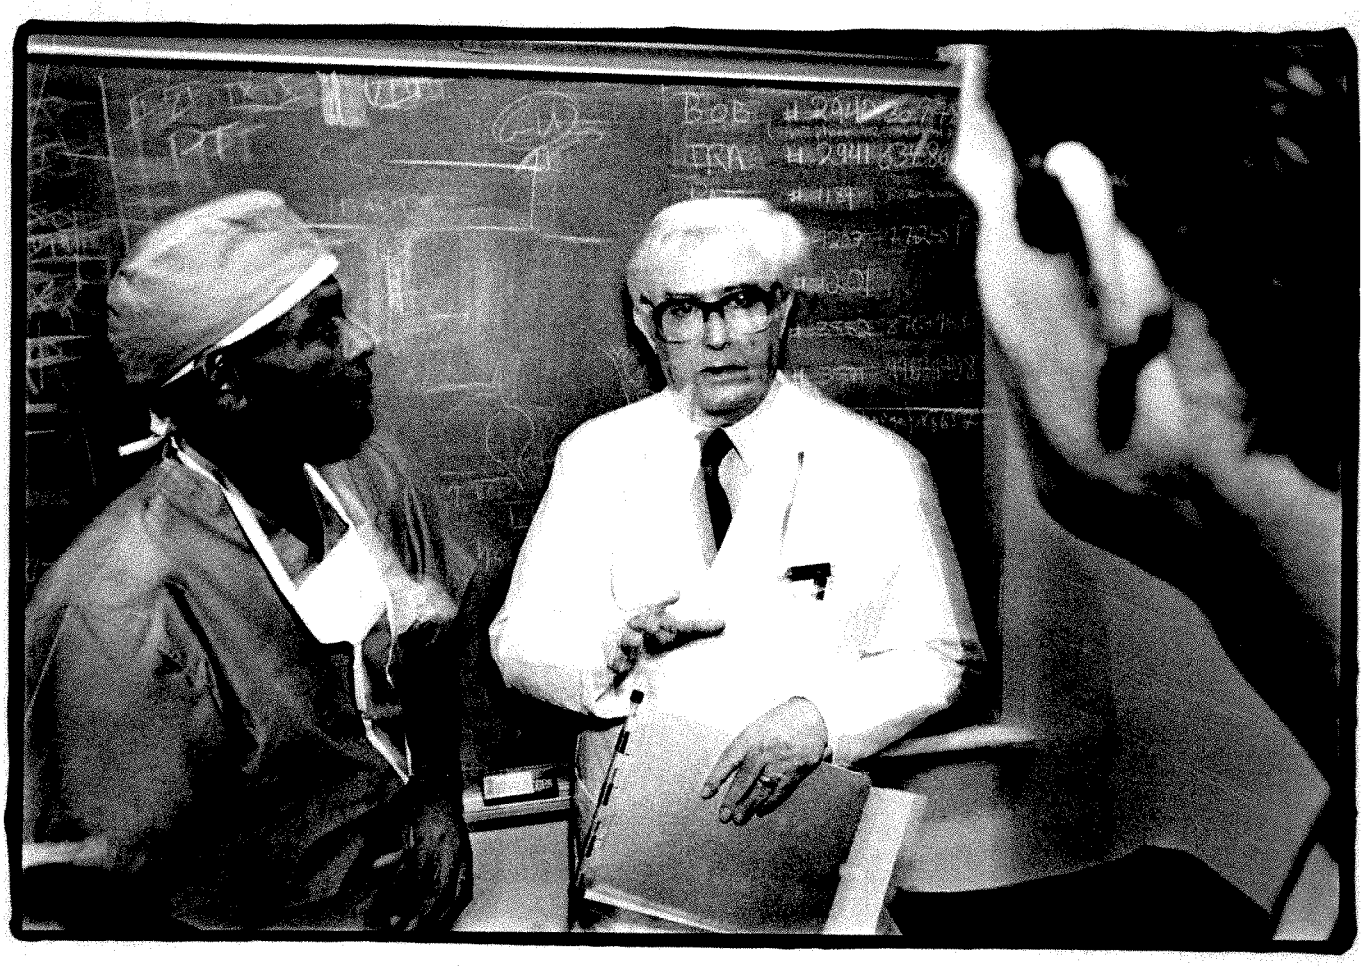
INDICATIONS AND USAGE
UNASYN is indicated for the treatment of infections due to susceptible strains of the designated microorganisms in the conditions listed below.
Skin and Skin Structure Infections caused by beta-lactamase producing strains of *Staphylococcus aureus*, *Escherichia coli*,* *Klebsiella* spp.* (including *K. pneumoniae**), *Proteus mirabilis*,* *Bacteroides fragilis*,* *Enterobacter* spp.,* and *Acinetobacter calcoaceticus*.*
Intra-Abdominal Infections caused by beta-lactamase producing strains of *Escherichia coli*, *Klebsiella* spp. (including *K. pneumoniae**), *Bacteroides* spp. (including *B. fragilis*), and *Enterobacter* spp.*
Gynecological Infections caused by beta-lactamase producing strains of *Escherichia coli*,* and *Bacteroides* spp.* (including *B. fragilis**).
*Efficacy for this organism in this organ system was studied in fewer than 10 infections.
While UNASYN* (ampicillin sodium/sulbactam sodium) is indicated only for the conditions listed above, infections caused by ampicillin-susceptible organisms are also amenable to treatment with UNASYN due to its ampicillin content. Therefore, mixed infections caused by ampicillin-susceptible organisms and beta-lactamase producing organisms susceptible to UNASYN should not require the addition of another antibiotic.



CONTRAINDICATIONS
The use of UNASYN is contraindicated in individuals with a history of hypersensitivity reactions to any of the penicillins.

WARNINGS
SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (ANAPHYLACTIC) REACTIONS HAVE BEEN REPORTED IN PATIENTS ON PENICILLIN THERAPY. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY AND/OR HYPERSENSITIVITY REACTIONS TO MULTIPLE ALLERGENS. THERE HAVE BEEN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE REACTIONS WHEN TREATED WITH CEPHALOSPORINS. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, UNASYN SHOULD BE DISCONTINUED AND THE APPROPRIATE THERAPY INSTITUTED.
SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE, OXYGEN, INTRAVENOUS STEROIDS, AND AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

PRECAUTIONS
General: A high percentage of patients with mononucleosis who receive ampicillin develop a skin rash. Thus, ampicillin class antibiotics should not be administered to patients with mononucleosis. In patients treated with UNASYN the possibility of superinfections with mycotic or bacterial pathogens should be kept in mind during therapy. If superinfections occur (usually involving *Pseudomonas* or *Candida*), the drug should be discontinued and/or appropriate therapy instituted.
Drug Interactions: Probenecid decreases the renal tubular secretion of ampicillin and sulbactam. Concurrent use of probenecid with UNASYN may result in increased and prolonged blood levels of ampicillin and sulbactam. The concurrent administration of allopurinol and ampicillin increases substantially the incidence of rashes in patients receiving both drugs as compared to patients receiving ampicillin alone. It is not known whether this potentiation of ampicillin rashes is due to allopurinol or the hyperuricemia present in these patients. There are no data with UNASYN and allopurinol administered concurrently. UNASYN and aminoglycosides should not be reconstituted together due to the *in vitro* inactivation of aminoglycosides by the ampicillin component of UNASYN.
Drug/Laboratory Test Interactions: Administration of UNASYN will result in high urine concentrations of ampicillin. High urine concentrations of ampicillin may result in false positive reactions when testing for the presence of glucose in urine using Clinitest™, Benedict's Solution or Fehling's Solution. It is recommended that glucose tests based on enzymatic glucose oxidase reactions (such as Clinistix™ or Testape™) be used. Following administration of ampicillin to pregnant women, a transient decrease in plasma concentration of total conjugated estriol, estriolglucuronide, conjugated estrone, and estradiol has been noted. This effect may also occur with UNASYN.
Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential.
Pregnancy
Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits at doses up to ten (10) times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to UNASYN. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. (See—Drug/Laboratory Test Interactions.)
Labor and Delivery: Studies in guinea pigs have shown that intravenous administration of ampicillin decreased the uterine tone, frequency of contractions, height of contractions, and duration of contractions. However, it is not known whether the use of UNASYN in humans during labor or delivery has immediate or delayed adverse effects on the fetus, prolongs the duration of labor, or increases the likelihood that forceps delivery or other obstetrical intervention or resuscitation of the newborn will be necessary.
Nursing Mothers: Low concentrations of ampicillin and sulbactam are excreted in the milk; therefore, caution should be exercised when UNASYN is administered to a nursing woman.
Pediatric Use: The efficacy and safety of UNASYN have not been established in infants and children under the age of 12.

ADVERSE REACTIONS
UNASYN is generally well tolerated. The following adverse reactions have been reported.
Local Adverse Reactions
Pain at IM injection site—16%. Pain at IV injection site—3%.
Thrombophlebitis—3%.
Systemic Adverse Reactions
The most frequently reported adverse reactions were diarrhea in 3% of the patients and rash in less than 2% of the patients.
Additional systemic reactions reported in less than 1% of the patients were: itching, nausea, vomiting, candidiasis, fatigue, malaise, headache, chest pain, flatulence, abdominal distension, glossitis, urine retention, dysuria, edema, facial swelling, erythema, chills, tightness in throat, substernal pain, epistaxis and mucosal bleeding.
Adverse Laboratory Changes
Adverse laboratory changes without regard to drug relationship that were reported during clinical trials were:
Hepatic: Increased AST (SGOT), ALT (SGPT), alkaline phosphatase, and LDH.
Hematologic: Decreased hemoglobin, hematocrit, RBC, WBC, neutrophils, lymphocytes, platelets and increased lymphocytes, monocytes, basophils, eosinophils, and platelets.
Blood Chemistry: Decreased serum albumin and total proteins.
Renal: Increased BUN and creatinine.
Urinalysis: Presence of RBC's and hyaline casts in urine.
The following adverse reactions have been reported with ampicillin-class antibiotics and can also occur with UNASYN:
Gastrointestinal: Gastritis, stomatitis, black "hairy" tongue, enterocolitis and pseudomembranous colitis.
Hypersensitivity Reactions: Urticaria, erythema multiforme, and an occasional case of exfoliative dermatitis have been reported. These reactions may be controlled with antihistamines and, if necessary, systemic corticosteroids. Whenever such reactions occur, the drug should be discontinued, unless the opinion of the physician dictates otherwise. Serious and occasional fatal hypersensitivity (anaphylactic) reactions can occur with a penicillin (see WARNINGS).
Hematologic: In addition to the adverse laboratory changes listed above for UNASYN, agranulocytosis has been reported during therapy with penicillins. All of these reactions are usually reversible on discontinuation of therapy and are believed to be hypersensitivity phenomena.

"We need gold-standard results that don't cost a fortune."

Lower antibiotic costs without lowering your standards. UNASYN costs at least 40% less per day than clindamycin/gentamicin or cefoxitin.[11] Yet UNASYN is at least as effective in a variety of mixed infections.*[3,12-19]

And in some studies versus combination therapy, patients treated with UNASYN spent fewer days in the hospital.[3,16,17]

So, look to UNASYN for highly effective, highly affordable therapy in mixed infections* every day.

THE PERMANENTE MEDICAL GROUP

NORTHERN CALIFORNIA

The Permanente Medical Group, the largest multispecialty group practice in the U.S., is undergoing explosive growth in its Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley. Our rapid increase in membership has created practice opportunities throughout the region for additional BC/BE Obstetricians and Gynecologists.

Our physician-managed group is part of the comprehensive Kaiser Permanente Medical Care Program. As a TPMG physician, you have access to the latest medical technology and resources, the support of colleagues in all subspecialties — and the opportunity to provide excellent health care without the burdens of managing a practice.

Join us in one of these facilities:

QUALITY

STABILITY

LEADERSHIP

GROWTH

SUPPORT

REWARDS

Santa Rosa — Opening new hospital featuring seven LDR's. Ten OB/GYN physicians and five nurse practitioners. Specialties include infertility, colposcopy, laser surgery and hysteroscopy. Call required once every nine nights. In Northern California's wine country, one hour north of San Francisco.

Santa Clara/Milpitas/Sunnyvale — 28 member department includes 3 perinatologists, GYN oncologist and reproductive endocrinologist. Ongoing clinical research. Our academic-oriented facility has an independent fully-accredited OB/GYN residency and serves as a core rotation for Stanford Medical Students. Academic appointments possible.

San Jose/Gilroy — Our 18 OB/GYN physicians average 3,000 deliveries per year and offer a full range of services including infertility, dysplasia and gyn-urology. On call approximately three nights per month. In-house Level II nursery; prenatal service shared with our nearby Santa Clara medical center. Satellite office in Gilroy. Located south of San Francisco and about one hour from the Monterey coast. The surrounding hills create a pleasant environment in which to live and work.

Hayward/Fremont — Full range of OB/GYN services with Level III L&D/ICN, 3000 deliveries yearly. Full time staff includes perinatologist and four neonatologists. Medical center and associated medical office located on east shore of San Francisco Bay with easy access to entire Bay Area.

Walnut Creek — Department of 15 physicians, a perinatologist and seven nurse practitioners. Two physicians on call daily. Teaching responsibilities for third year residents affiliated with the University of California at San Francisco. Clinical appointments at UCSF also available. Expansion plans include a large ICN, and within five years, a completely new hospital.

Martinez/Antioch — Southern California climate, Northern California charm, Bay Area location. Primarily in/outpatient GYN, outpatient OB. Seven physicians and four nurse practitioners in office and hospital practice. Deliver at the Walnut Creek Medical Center. High-risk pregnancy clinic at Martinez. Labor room call once or twice a month.

Vallejo/Fairfield/Napa — Seventeen physicians and four nurse practitioners at these facilities. Approximately 2,900 deliveries performed each year at the Vallejo medical center. Usual call is every eighth night. Affiliated with David Grant Medical Center residency program at Travis Air Force Base. Our area offers diverse lifestyle options, with both recreational and cultural attractions nearby.

San Rafael/Petaluma — OB/GYN services are available at both the San Rafael Medical Center and the new Petaluma medical offices which opened in January of 1989.

South Sacramento — Eight physicians and four nurse practitioners serve 104,000 members in fast-growing Central Valley area. Planning new family-oriented L&D facilities.

KAISER PERMANENTE
Good People. Good Medicine.

TPMG offers many benefits: scheduled time off with cross-coverage provided by your colleagues, continuing education, malpractice insurance, a substantial retirement program and special arrangements for physicians transferring from established practice. A protocol for managing severe preeclampsia in the second trimester

Baha M. Sibai, MD, Sherif Akl, MD, Fiona Fairlie, MD, and Michael Moretti, MD
Memphis, Tennessee

One hundred nine patients with severe preeclampsia in the second trimester were studied. Pregnancy termination was recommended for those with gestational age ≤24 weeks (n = 25), whereas expectant management with aggressive maternal and fetal monitoring was recommended for those with gestational age >24 but ≤27 weeks (n = 84). Ten of the 25 women in the early pregnancy group accepted termination and 15 elected to continue the pregnancy. The overall perinatal survival in the latter 15 patients was 6.7%, and maternal complications developed in six patients. Thirty of the 84 patients in the late second-trimester group had immediate delivery, and 54 had expectant management. The average length of pregnancy prolongation in the expectant group was 13.2 days (range, 4 to 28 days). Compared with the immediate delivery group, the expectant management group had significantly higher perinatal survival (76.4% versus 35.%), significantly higher birth weights (880 versus 709 gm), and a lower incidence of neonatal complications. There were no differences between the two groups with regard to maternal complications. Expectant management with aggressive monitoring of maternal and fetal status at a perinatal center improves perinatal outcome in patients with severe preeclampsia with gestational age >24 but ≤27 weeks. (Am J Obstet Gynecol 1990;163:733-8.)

Key words: Preeclampsia, second trimester, expectant management

Severe preeclampsia that develops in the second trimester is associated with high perinatal mortality and morbidity.[1-3] Aggressive management with immediate delivery results in high neonatal mortality. In addition, significant neonatal complications develop in all surviving newborn infants and prolonged hospitalization in neonatal intensive care units is necessary. Moreover, a significant proportion of surviving infants have long-term disability.[1,4] Conversely, attempts to prolong pregnancy may result in fetal death or asphyxial damage in utero.[1,3]

We previously reported on 60 such pregnancies that had conservative management in an attempt to prolong pregnancy. The overall perinatal survival was only 13%. However, for patients who had the disease before 25 weeks' gestation, the survival rate was 3.2% (1/31), whereas it was 27.6% (9/29) for patients in whom the disease developed at or beyond 25 weeks' gestation. In addition, maternal morbidity was significant with the majority of complications in patients in whom the disease developed early in the second trimester and in patients who had conservative management at local hospitals before referral to the perinatal center. As a result, a new protocol for management of these patients was initiated in 1985. The purpose of this article is to report pregnancy outcome in 109 such patients since the institution of this new protocol at this center.

Material and methods

The study included 109 patients with severe preeclampsia developing at or before 27 weeks' gestation who were managed at the E. H. Crump Women's Hospital and Perinatal Center between January 1985 and June 1989. Severe preeclampsia was defined as reported previously from this center.[2] All patients had a live fetus at the time of inclusion, and all had documented evidence of the disease for less than 48 hours before this management. Patients with maternal or fetal indications necessitating immediate delivery on admission were not included. For example, patients with thrombocytopenia (platelet count $<10 \times 10^3/mm^3$, HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, pulmonary edema, evidence of fetal distress, oligohydramnios) were excluded. In addition, patients who were managed conservatively at a local hospital before transfer to the center were also excluded. Most patients in this group required immediate delivery for maternal or fetal indication as stated above.

All patients were first admitted to the labor and delivery area and carefully evaluated. They were then counseled regarding maternal and perinatal risks and benefits from expectant management. Pregnancy ter-

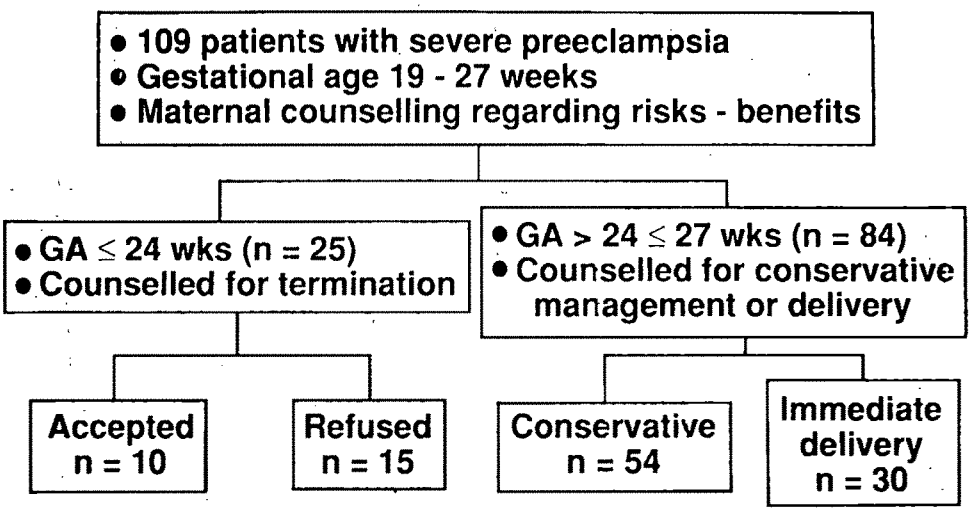

Fig. 1. Summary of 109 patients with severe preeclampsia. Patients were counseled with regard to termination or expectant management on basis of gestational age at time of admission.

mination was recommended for patients with gestational ages ≤24 weeks; aggressive expectant management monitoring was recommended if the gestational age was >24 but ≤27 weeks. The study patients were then subdivided into four groups (Fig. 1). One group (n = 10) with gestational age ≤24 weeks accepted immediate termination of pregnancy. These patients received intravenous magnesium sulfate to prevent convulsions, intravenous hydralazine to control severe hypertension, and prostaglandin E vaginal suppositories to terminate pregnancy. A second group (n = 15) with similar gestational age elected to continue with expectant management.

A third group (n = 30) with gestational age >24 weeks had immediate delivery either because of patient's desire (n = 21) or because of attending staff desire (n = 9). These patients had stabilization of maternal condition, continuous monitoring in labor and delivery, and received corticosteroids to accelerate fetal lung maturity. They were then delivered 24 hours after the last dose of steroids if possible. The remaining patients (n = 54) with gestational age >24 weeks elected expectant management.

Patients who chose conservative management were monitored in the labor and delivery area for a minimum of 24 hours. Initial drug therapy consisted primarily of intravenous magnesium sulfate to prevent convulsions and bolus injections of hydralazine or labetalol to maintain diastolic blood pressure below 100 mm Hg. Intravenous fluids and urinary output were carefully monitored during the observation period. After this observation period patients were then transferred to the high-risk antepartum floor. Oral antihypertensive medications were then used to maintain the diastolic pressure between 90 and 100 mm Hg. The antihypertensive drugs used were methyldopa, hydralazine, and labetalol initially; nifedipine was used during the last 2 years of the study.

Fetal viability was confirmed on admission in all cases. Gestational age was determined by the combined use of last menstrual period and early ultrasonographic measurements. Fetal growth was measured ultrasonographically every 10 to 14 days when appropriate (in patients continuing their pregnancies beyond this point). The presence of severe fetal growth retardation (estimated fetal weight <5th percentile for our population) was considered a fetal indication for delivery. Fetal well-being was assessed by daily biophysical profile and nonstress testing. The biophysical profile was evaluated according to the criteria of Manning et al.[5] The biophysical profile was considered abnormal if the score was ≤4/8 on two occasions 6 hours apart. Because the nonstress test is nonreactive in the majority of fetuses with these gestational age, the reactivity of the nonstress test was not considered in the biophysical profile. Thus the total score used was 8. The nonstress test was considered abnormal if the test was nonreactive in association with persistent spontaneous decelerations. The presence of either an abnormal nonstress test result or an abnormal biophysical profile score was considered a fetal indication for delivery. Corticosteroids were used routinely to accelerate fetal lung maturity in all cases when the gestational age was >25 weeks.

Maternal evaluation included frequent blood pressure measurements and daily weight. All patients were instructed to report the presence of persistent headaches, visual disturbances, or epigastric pain. In addition, they were instructed to report the presence of uterine contractions, abdominal pain, vaginal bleeding, or significant changes in fetal movements (absent fetal

Abruptio placentae	2	13.3
Eclampsia	1	6.7

movements for 4 hours during the day). The presence of absent fetal movement was evaluated by the nonstress test and biophysical profile and was then managed according to the findings of these tests. Laboratory evaluation included serial measurements of creatinine clearance and 24-hour excretion of protein. All patients also had daily measurements of hematocrit, platelet count, coagulation profile, and liver enzymes levels. Thrombocytopenia was defined as a platelet count of $<100 \times 10^3/mm^3$. The combination of hemolysis, elevated liver enzymes, and low platelet count was defined as the HELLP syndrome as described previously from this center.[6] Maternal indications for delivery included the development of convulsions, thrombocytopenia only, HELLP syndrome, pulmonary edema, vaginal bleeding (in absence of placenta previa), and persistent epigastric pain.

Clinical data on the infants included gestational age, birth weights, Apgar scores, cord blood gases, and neonatal complications. An infant was considered to be small for gestational age if the birth weight was below the 10th percentile according to the criteria of Brenner et al.[7] All newborn infants were followed up until discharge from the intensive care nursery. Surviving infants were subsequenty seen at our follow-up clinic and interval history and physical examination was available at each visit. Children with diagnosed cerebral palsy or hydrocephalus were considered neurologically abnormal; all others were considered to have normal development.[4]

For comparative purposes pregnancy in patients with gestational age >24 weeks was compared with the respective outcome in the patients with similar gestational age who had immediate delivery. Results were analyzed by Student's t test to compare means of normally distributed data, χ^2 test to compare frequencies, and Fisher's exact test when appropriate. Differences were considered to be significant for values of $p < 0.05$.

Results

During the period of this study 121 patients with severe preeclampsia that developed in the second trimester were delivered at this center. Twelve patients required immediate delivery on admission for either maternal or fetal reasons. Three patients presented with eclampsia, three had HELLP syndrome, one had pulmonary edema, one had severe thrombocytopenia, three had abruptio placentae, two had fetal death on admission, and four had evidence of fetal distress (some patients had more than one complication). The average gestational age at time of delivery in these patients was 25.2 weeks (range, 20 to 27 weeks). These pregnancies resulted in 5 stillbirths and six neonatal deaths (overall perinatal survival of 8.3%).

Ten patients with gestational age ≤24 weeks accepted termination of pregnancy and thus received prostaglandin E_2 vaginal suppositories. All pregnancies resulted in stillbirths and there were no maternal complications in this group. The mean gestational age in these 10 patients was 21.8 weeks (range, 18 to 23.5 weeks), and the mean birth weight was 422 gm (range, 210 to 580 gm). There was no evidence of hydropic degeneration of the placenta in any of these pregnancies.

Fifteen patients with gestational age ≤24 weeks chose expectant management. Tables I and II summarize the gestational age at time of onset of the disease, gestational age at time of delivery, and the overall maternal and perinatal outcome in these patients. There were 11 stillbirths and three neonatal deaths (overall perinatal survival of 6.7%) in these patients. The three neonatal deaths occurred in infants with birth weights of 440, 470, and 650 gm. The surviving infant had a birth weight of 740 gm and stayed in the neonatal intensive care unit for 95 days. This infant had normal findings on follow-up at 4 years. In addition, four patients (27%) had one or more of the maternal complications listed in Table II.

Of the 84 patients with severe preeclampsia at >24 weeks' gestation 54 had conservative management and 30 had immediate delivery (Fig. 1). The groups were similar with regard to maternal age (23.8 ± 6.3 vs 23.0 ± 6.0 years), percent nulliparous (63% vs 59%), and frequency of chronic hypertension (33% vs 30%).

Table III compares the pregnancy outcome in these patients. Except for the one patient with fetal death, all pregnancies were delivered by cesarean section. The conservative management group had significantly

Seizures	3	5	5	16

*$p < 0.007$, odds ratio 3.6 : 1.

higher mean gestational age and birthweight at time of delivery. The 54 pregnancies in the conservative group resulted in 55 births (one set of twins). There was one stillbirth and 12 neonatal deaths (overall perinatal loss of 23.6%) in this group. The 30 pregnancies in the immediate delivery group resulted in 31 births (one set of twins). There were no stillbirths in this group, and the overall neonatal loss was 64.5%. Thus the conservative treatment group had a significantly higher perinatal survival than the immediate delivery group (76.4% vs 35.5%, $p < 0.0005$). In addition, the conservative group had a significantly higher Apgar score and pH, and a significantly lower number of days in the newborn center than the immediate delivery group.

Table IV compares the neonatal complications between the two groups. The conservative group had a significantly lower incidence of neonatal intraventricular hemorrhage than the other group (41% vs 71%, $p < 0.007$). The conservative group also had a lower incidence of neonatal seizures (5% vs 16%); however, this difference was not significant.

There were 42 surviving infants in the conservative treatment group with a mean (±SD) follow-up of 21.8 ± 15 months (range, 3 to 48 months). Five infants (11.9%) had significant neurologic deficits. Eleven surviving infants in the immediate group had follow-up of 18.3 ± 16.1 months (range, 3 to 48 months). Three (27.3%) had significant neurologic deficits. The difference between the two groups was not significant because of the small number of infants in each group.

Maternal outcome. Maternal complications were the indication for delivery in 12 women (22.2%) in the conservative management group. The remaining patients were delivered for fetal indications. These 12 patients had a total of 17 complications (HELLP syndrome, eclampsia, abruptio placentae, or thrombocytopenia). Conversely, six patients (20%) in the immediate delivery group had a total of eight similar maternal complications. Table V compares the maternal complications between the two groups. There were no differences regarding any of the categories studied.

Comment

Severe preeclampsia in the second trimester is an infrequent complication of pregnancy. Most practicing obstetricians have limited experience in managing such patients. Pregnancy outcome in these patients depends on gestational age at time of onset of the disease, as well as maternal and fetal status at time of presentation to a perinatal center.[1, 4, 8] Optimum management

usually depends on balancing the risks to the mother and fetus from expectant management against the risks of extreme prematurity from immediately delivery.

This study was designed to evaluate a new protocol for management of such patients that depended on the gestational age at time of onset of severe preeclampsia. Pregnancy termination was recommended for the 25 patients who had the disease at ≤24 weeks' gestation; however, 15 (60%) refused such recommendation. As a result these patients require aggressive monitoring of maternal and fetal status and thus should be referred to a perinatal center with adequate maternal and neonatal intensive care facilities. The overall perinatal survival rate in these patients was only 6.7% (1/15), and maternal morbidity was significant (27%). These findings argue against any potential benefit from conservative management in these patients. The findings are in agreement with our prevoiusly reported experience.[1] In addition. Odendaal et al.[3] reported a zero perinatal survival rate after conservative management in 11 such patients.

Conservative management was recommended for the 84 patients who had the disease at >24 but ≤27 weeks' gestation; however, 30 (36%) had immediate delivery because of refusal of conservative management either by the patient or by the attending physician. This study demonstrated that it was possible to prolong pregnancy by an average of 2 weeks (range, 4 to 38 days) in the group who had conservative management. This prolongation in pregnancy was associated with significant improvement in both perinatal mortality and morbidity without a significant increase in maternal morbidity when compared with the group who had immediate delivery. The perinatal survival rate in the expectant group was 76.4% compared with 35.5% in the group that had immediate delivery. In addition, the infants in the conservative management group had a lower incidence of intraventricular hemorrhage (41% vs 71%) and a lower number of days in neonatal intensive care unit (70 vs 115 days). In this study a small number of infants in both groups had a follow-up period beyond 2 years of age. As a result we restricted our comparisons to the presence of significant neurologic deficit. Thus our data cannot be used to draw any conclusions with regard to any differences between the two groups as it relates to the presence of subtle or minimal neurologic abnormalities. It is interesting to note that the conservative group had a higher incidence of bronchopulmonary dysplasia (33%) than the immediate group (19%). This difference may be a result of the fact that 11 infants in the immediate group died within 1 week of delivery (before the onset of bronchopulmonary dysplasia). Conversely, only three infants in the conservative treatment group died within 1 week of delivery.

Table V. Maternal complications

Variable	*Conservative group (n = 54)*		*Immediate group (n = 30)*	
	No.	*%*	*No.*	*%*
HELLP syndrome	7	13.0	4	13.3
Eclampsia	3	5.6	1	3.3
Abruptio placentae	3	5.6	2	6.7
Thrombocytopenia only	4	7.4	1	3.3

It is important to note that delivery was delayed >1 week in 39 patients and >2 weeks in 18 patients in the conservative management group. A gain of 1 to 2 weeks before delivery could have been of great benefit for fetuses with gestational ages between 24 and 25 weeks. In these pregnancies a gain of 2 weeks could have been the difference between a live infant with intact survival or an imminent neonatal death. These data should be useful in counseling such patients.

Our findings indicate that the nonstress test and the biophysical profile are reliable in assessing the fetal condition during conservative management in the group with gestational age >24 weeks. In this study monitoring was started as soon as the patient was admitted and performed daily regardless of gestational age. Among the 54 pregnancies that had this intensive monitoring, there was only one fetal death from abruptio placentae. Conversely, the diagnosis of abruptio placentae was suspected and later confirmed in two other patients who demonstrated repeat decelerations during the nonstress test. It is important to note that 42 (78%) of the pregnancies in this group were delivered for fetal indications as determined by the biophysical profile or the nonstress test. In addition, it is important to note that the institution of early and intensive fetal monitoring in this study is responsible for the improved perinatal outcome compared with the results reported from this center in an earlier study.[1] An important difference between the two studies is the onset and frequency of fetal monitoring. In the earlier report monitoring was not commenced until 27 weeks' gestation and most perinatal deaths occurred before that time.

In an earlier report[1] we described a high incidence of maternal complications among 60 patients with severe preeclampsia who had conservative management. Significant maternal complications included abruptio placentae (27.7%), eclampsia (16.7%), the HELLP syndrome (16.7%), and acute renal failure (5%). The incidence of abruptio placentae for patients with conservative management in this study was 5.6%, and the incidence of eclampsia was 5.6%. None of the patients had acute renal failure. It is important to emphasize that the institution of early and intensive maternal mon-

itoring in this study is responsible for the improved maternal outcome compared with the results reported in the early study and the results obtained in the 12 patients who required immediate delivery on admission (excluded patients). In the earlier report most patients had conservative management at local hospitals, and patients were not referred until onset of maternal complications. These findings underscore the importance of referring such patients to tertiary care centers with appropriate intensive care facilities once the diagnosis is made.

In summary, the development of severe preeclampsia in the second trimester is associated with high perinatal mortality and morbidity and significant maternal morbidity. Patients should be referred to a tertiary care center once the diagnosis is established. Conservative management with aggressive monitoring of maternal and fetal status is possible in a *select* group of these patients, primarily those with gestational age beyond 24 weeks. This management should be practiced *only* in a tertiary care center with adequate intensive care facilities.

Catastrophic complications of previous cesarean section

Cynthia Chazotte, MD, and Wayne R. Cohen, MD

Bronx, New York

Of 711 patients who were delivered after one or more previous cesarean sections, 17 (2.4%) had an extremely serious complication. Uterine rupture and placenta previa or placenta accreta with accompanying hemorrhage were the major contributors to mortality and major morbidity. Nine uterine ruptures occurred, including five associated with labor with a low transverse uterine scar and one with an unknown scar (1.4% of trials of labor). There were two cases of placenta previa and five with varying degrees of placenta accreta. The nature and frequency of the observed complications emphasize the potentially serious remote consequences of cesarean section. (Am J Obstet Gynecol 1990;163:738-42.)

Key words: Previous cesarean, uterine rupture, placenta accreta, cesarean complications

Many women with a uterine scar from previous cesarean section become pregnant and are thereby exposed to certain risks. Although there is general agreement that pregnancy and labor after cesarean delivery are reasonable and safe,[1] precise quantification of the risk attributable to a prior cesarean section is difficult. Most studies suggest that uterine rupture or placenta accreta with potentially serious consequences for the mother or fetus occur infrequently.[2-8] As experience with patients with prior cesarean sections has grown, the ability to assess the likelihood of a serious complication in a subsequent pregnancy has been refined. We performed a retrospective analysis to quantify the risk of catastrophic complications in a pregnancy after previous cesarean delivery.

Methods

From January 1986 to June 1989 there were 10,835 deliveries at the Bronx Municipal Hospital Center, of which 711 (6.6%) involved patients with a prior cesarean section. Vaginal birth after cesarean section was attempted by 424 women and was successful in 312 (73.6%). We defined a catastrophic complication related to a prior cesarean section as one that resulted in maternal or fetal death; hemorrhage necessitating transfusion of ≥5 units of red blood cells, hysterectomy, or major artery ligation; or uterine rupture necessitating emergency surgery or associated with an extruded fetus or neonatal depression (Apgar score <6 at 5 minutes). The diagnosis of placenta accreta was accepted only if confirmed histologically in an extirpated uterus.

Seventeen (2.4%) women with a previous cesarean section who had one or more catastrophic complications during a subsequent pregnancy were identified from the hospital's computerized discharge data system and the chronologic birth record. The medical records from these 17 cases were reviewed. In addition, one or both authors was involved in the management of most of the complications and was thus familiar with the clinical details.

Results

Among the 17 identified cases with serious complications (Table I), 10 (59%) had a previous low transverse uterine incision. Eight patients (47%) had more than one prior cesarean delivery. Twelve (71%) infants were delivered preterm, and eight required admission to the neonatal intensive care unit.

There were two maternal and three fetal deaths among the study patients (Table II). One mother died from uncontrollable intraoperative hemorrhage during repeat cesarean section. She had an extensive placenta previa and percreta after two prior uncomplicated low-segment cesarean sections. The other maternal death was from a massive pulmonary embolus 4 weeks after cesarean hysterectomy for rupture of a previous vertical uterine scar identified at elective repeat cesarean. Two of the fetal deaths followed uterine rupture with complete extrusion of the fetus into the peritoneal cavity. The third fetal death involved spontaneous exsanguinating maternal hemorrhage at 22 weeks' gestation. This required cervical dilatation and fetal evacuation followed by internal iliac artery ligation and hysterectomy for control. Thirteen units of blood were transfused. The placenta was implanted as a central previa.

Serious hemorrhage occurred in 11 women and necessitated hysterectomy in eight. In three patients the hemorrhage was caused by uterine rupture and in the others by placenta previa, often in association with some degree of placenta accreta. Only two of the hemorrhages occurred during a planned trial of labor. In four of the patients with hemorrhage, all of whom had placenta previa or accreta, bilateral uterine or internal iliac artery ligation was performed; hysterectomy was thus avoided in one case.

Nine of the 17 women with serious complications had uterine rupture; these constituted 1.3% of all patients delivered after one or more previous cesarean sections. Six ruptures were associated with trial of labor (1.4% of all patients who were allowed a trial of labor). Among these six ruptures, five were likely to have occurred during labor. One case was undoubtedly present before induction of labor at 33 weeks for presumed intrauterine fetal death and suspected abruptio placentae. Recognition of the misdiagnosis in this case led to exploratory laparotomy and identification of the rupture and extruded fetus. Three of the five patients whose ruptures probably occurred during a trial of labor had received oxytocin.

In four of the cases of uterine rupture the umbilical cord or entire products of conception were extruded from the uterine cavity; of these cases, two fetuses were stillborn and two had Apgar scores <6 at 5 minutes. In the five cases of rupture in which extrusion did not occur, only one infant had neonatal depression. In six of the nine women with uterine rupture it was deemed appropriate to repair the uterus rather than to perform hysterectomy.

Four of the six ruptures in uteri with prior low transverse incisions appeared to occur along the old scar and extended laterally into the vascular tissue of the broad ligament. One extended vertically from the lateral corner of the old scar cephalad into the fundus and caudad to the cervix. Another extended vertically in the midline. We were unable to determine in this patient whether during the previous surgery the transverse hysterotomy had been extended vertically. The prior incision known to have been vertical ruptured along the scar, and of the two cases in which the prior incision type was unknown, one ruptured vertically and the other both vertically and laterally into the broad ligament.

Comment

We reviewed the incidence and nature of extremely serious complications of pregnancy after cesarean section. Overall, one patient in 42 with one or more prior cesarean deliveries had such a complication. The risk of maternal or fetal death in our series was approximately one in 143 pregnancies with a history of previous cesarean delivery.

We found a higher rate of some complications than has been reported from other institutions. For example, the rate of placenta previa with accreta in our series (7.0/1000 patients with prior cesarean sections) was

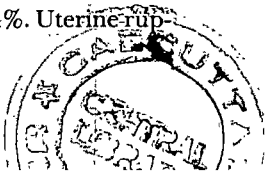
can low-socioeconomic population), to the well-known problem of complete case finding in retrospective studies,[14] to a currently more liberal attitude toward allowing a trial of labor, or to the rigor with which complications have been defined in various studies. We are confident that we identified all cases at our institution that were delivered during the study period and met the study criteria.

We considered that our approach to labor, which involves the careful use of oxytocin for induction or stimulation of labor based on the same criteria we use in women without a cesarean section scar,[15] might have led to a high rate of uterine rupture. The fact that our uterine rupture frequency among women before labor was also higher than that of many previous reports makes it more likely that other factors are operative. Although data from several institutions support the safety of oxytocin stimulation during trials of labor,[16, 17] definitive information with regard to this issue is lacking.



Of the patients who had uterine rupture during labor, it is of interest that the three women who had epidural anesthesia nevertheless had pain attributable to the rupture. Two cases of rupture had what might be considered prolonged arrest disorders and showed no response to 4 and 10 hours of oxytocin administration, respectively, before delivery. These cases suggest that arrest disorders might indicate or predispose a patient to uterine rupture, or that perhaps a trial of labor should be discontinued if there is not a prompt response to uterine stimulation. One rupture occurred during sedation for prolonged latent phase labor, and another was noted during an evaluation of postpartum hemorrhage after a normal labor and delivery. Thus rupture can occur with relatively mild uterine activity, can be asymptomatic during labor, and does not preclude normal dilatation and descent. These conclusions must be tempered by the fact that we could not always determine precisely when during the course of parturition some ruptures occurred.

Interestingly, four instances of uterine rupture were initially diagnosed as abruptio placentae with fetal distress. In view of this, we think that clinical signs of abruptio placentae in a woman with a previous cesarean scar should always raise concerns about the possibility of uterine rupture.

The significance of our finding that four of the nine uterine ruptures in our series occurred in patients whose previous cesarean section was performed preterm is uncertain. It could imply that cesarean section in a uterus before term confers increased risk of subsequent rupture, perhaps because the lower uterine segment is less likely to have been well developed.

The striking frequency of placenta previa and placenta accreta in this series is consistent with the previously observed predilection of the placenta to implant in the vicinity of the uterine scar and for invasion of the myometrium by trophoblast to occur.[6] These cases and the uterine ruptures often required urgent and extensive surgery, including hysterectomy and ligation of major pelvic arteries. Physicians caring for patients with cesarean section scars should be comfortable performing these procedures and handling their potential complications.

In summary, we found the frequency of very serious complications in a series of pregnancies undertaken after previous cesarean section to be 2.4%. Uterine rup-

ture and placenta previa or various degrees of placenta accreta were the major contributors to mortality and serious morbidity. Trials of labor in women with previous low transverse cesarean sections contributed to 56% of the uterine ruptures, but several occurred before labor and would thus not necessarily have been prevented by elective repeat cesarean section. The information provided by this study may be useful in assessing risks of pregnancy with a previous cesarean. More importantly, the observed frequency and nature of complications in subsequent pregnancies, particularly in women with more than one prior cesarean delivery, emphasizes the importance of performing cesarean section only when the benefits to be accrued outweigh potential risks.

Antibiotic therapy in preterm premature rupture of membranes: A randomized, prospective, double-blind trial

Matthew M. Johnston, MD,[a] Luis Sanchez-Ramos, MD,[a] Arthur J. Vaughn, MD,[b] Mark W. Todd, PharmD,[c] and Guy I. Benrubi, MD[a]

Jacksonville, Florida

The use of antibiotics in the management of preterm, premature rupture of membranes remains controversial. By use of a prospective randomized double-blind design we investigated the maternal-fetal benefits associated with antibiotic therapy in 85 women with premature rupture of membranes at 34 weeks' estimated gestational age. In the treatment group 40 patients received intravenous mezlocillin for 48 hours followed by oral ampicillin until delivery. In the control group 45 patients received intravenous and oral placebo. Patients who received antibiotics had chorioamnionitis and endometritis less frequently than the control group ($p < 0.01$ and $p < 0.05$). Pathologic examination of the placentas showed a lower incidence of chorioamnionitis in the treatment group ($p < 0.05$). The period from premature rupture of membranes to delivery (latency) was prolonged with antibiotics ($p < 0.05$) and resulted in significant weight gain in the infants in the antibiotic group ($p < 0.0001$). These infants also had higher 1- and 5-minute Apgar scores. Clinically suspected sepsis, respiratory distress syndrome, intraventricular hemorrhage, perinatal death rate, and prolonged hospitalization (>30 days) were also increased in the control group. (AM J OBSTET GYNECOL 1990;163:743-7.)

Key words: Antiobiotics, premature rupture of membranes, preterm

Preterm, premature rupture of the fetal membranes is associated with significant perinatal morbidity and mortality. Women with preterm premature rupture of membranes often have chorioamnionitis and postpartum endometritis-myometritis. The infants frequently have respiratory distress syndrome (RDS), sepsis, intraventricular hemmorrhage, or necrotizing enterocolitis. An infant with any of these complications must be admitted to a neonatal intensive care unit. The costs of caring for these infants are high with prolonged hospitalization. At the University Medical Center in Jacksonville 3% of all deliveries are associated with premature rupture of membranes at <34 weeks' gestation. The perinatal mortality rate as a result of preterm premature rupture of membranes at University Medical Center in 1987 was 129/1000 live births. Neonatal sepsis, RDS, and intraventricular hemorrhage were frequent complications.[1]

Previous publications suggest that a large proportion of cases with premature rupture of membranes are the result of occult infections.[2-6] *Neisseria gonorrhoeae* and group B streptococcal colonization of the cervix have been associated with an increased risk of premature rupture of membranes. An occult infection of the cervix may initiate a sequence of biochemical pathways leading to premature rupture of membranes and subsequent labor.[4] Because of this risk of occult infection use of tocolytics and steroids in premature rupture of membranes is discouraged.[7, 8] A few studies have focused attention on the use of antibiotics in premature rupture of membranes.[9-13] However, only two studies could be found that used a prospective, double-blind, randomized design.[12, 13] Both showed no benefits to the infants when antiobiotics were used. Two recent prospective randomized studies examined ampicillin prophylaxis in preterm premature rupture of the membranes.[14, 15] These showed benefits to the infants when antibiotics were used. However, these were not double-blind studies, and some patients underwent tocolysis, some received steroids, whereas others had both or neither modes of therapy.

The purpose of our study was to investigate whether antibiotics administered to women with preterm premature rupture of membranes (<34 weeks) would decrease maternal or perinatal morbidity and mortality, or both.

Material and methods

The study population included all women who came to the University Medical Center–Jacksonville, Florida labor and delivery suite with premature rupture of the membranes from 20 to 34 weeks gestational age. The

6/6/22349

study was performed with approval of the University Medical Center Institutional Review Board. Only mothers with singleton gestations between 20 and 34 weeks' gestational age with premature rupture of membranes who signed an informed consent were included. Premature rupture of membranes was confirmed by sterile speculum examination for pooling, ferning, and Nitrazine paper testing. Patients were excluded from the study if they had an allergy to penicillin, were taking antibiotics at the time of premature rupture of membranes, had fever >100.4° F, had signs and symptoms of chorioamnionitis, were in active labor (defined as three or more contractions per 10-minute period for 1 hour, or if they presented with cervical dilation >3 cm confirmed at the time of sterile speculum exam. Fetal indications for exclusion were the presence of fetal distress, defined as repetitive late deceleration or sustained bradycardia, and congenital abnormality noted on ultrasonographic examination.

After the patient was included in the study a medical history was obtained and physical examination was performed. The history included the mother's age, race, gravidity, parity, estimated gestational age by last menstrual period, date and time of premature rupture of membranes, presence of contractions, abdominal pain, fever, presence of any maternal illness or pregnancy-related complications, use of medications, and allergies. A complete physical examination including abdominal palpation for uterine tenderness and fundal height measurement and sterile speculum examination with fern and Nitrazine paper testing was performed. If fluid was present at the vaginal vault, it was collected for fetal lung maturity evaluation. The cervix was inspected for dilatation and cultures for gonorrhea and streptococcus were obtained. Digital vaginal examination was not allowed. The estimated gestational age and fetal weight, presentation of the fetus, and the presence or absence of oligohydramnios were documented by ultrasonography. A biophysical profile was obtained including a nonstress test. Laboratory studies included a complete blood cell count with differential, serum electrolytes, rubella, serologic tests for syphilis, blood type, and antibody screen, urinalysis, and urine culture and sensitivity. Randomization was accomplished by a table generated by consecutive coin toss; the randomization schedule was kept in the pharmacy and was unavailable to the clinicians.

After 8 hours of monitoring if there was no evidence of labor, chorioamnionitis, or fetal distress as previously defined the patient was transferred to the antepartum unit on strict bed rest; vital signs and fetal heart tones were recorded every 2 hours. Physical examination, a biophysical profile, and complete blood count were completed daily. If any evidence of labor or chorioamnionitis developed the patient was transported to the labor and delivery unit for management. No tocolytic agents or steroids were given. If labor continued the patient was allowed to deliver spontaneously. Chorioamnionitis was diagnosed by a temperature >100.4° in combination with either uterine tenderness, fetal tachycardia, foul-smelling vaginal discharge, or a white blood cell count >20,000/mm^3. In the presence of chorioamnionitis, antibiotics were not given if delivery was imminent. However, if delivery did not appear to be imminent, intravenous gentamicin and ampicillin were started as well as oxytocin induction or augmentation when appropriate. At that time the study drug was discontinued.

In those patients in whom labor or chorioamnionitis did not develop, evidence of fetal distress by external auscultation, biophysical profile, or nonstress testing became an indication for immediate transport to the labor and delivery unit for management. Fetal distress was diagnosed by persistent late decelerations, prolonged fetal bradycardia, or a score of <4 on biophysical profile. Delivery was expedited by appropriate methods in accordance with standard obstetric practice for persistent fetal distress.

If the initial cervical cultures for B-hemolytic streptococci or gonorrhea were positive, the study drug was discontinued and the patient received intravenous ampicillin or other appropriate antibiotic coverage for penicillin-resistant gonorrhea. However, the patient was not removed from the group to which she had been randomized and was included in the statistical analysis at the completion of the study. When fetal pulmonary maturity was suspected, a repeat amniotic fluid sample from the vagina or by amniocentesis was sent for phosphatidylglycerol determination or the lecithin/sphingomyelin ratio. Evidence of pulmonary maturity was an indication for induction of labor in fetuses >34 weeks' gestation.

Spontaneous delivery was allowed for vertex presentations. Malpresentations were delivered by cesarean section. At delivery the infant's age was estimated according to the Dubowitz scoring system, arterial cord gas studies were obtained, and cultures were obtained from the placenta 1 cm within the fetal and maternal surfaces. The fresh placenta was sent for histologic examination for funisitis, amnionitis, and chorioamnionitis.[16] At delivery the study drug was discontinued and the mother was transported to the postpartum unit and discharged home on the second postpartum day. Endometritis-myometritis was diagnosed by a temperature of 100.4° F on at least two occasions after the first 24 hours after delivery associated with uterine tenderness and no other focus of infection. If endometritis-myometritis was diagnosed the mother received gentamicin and clindamycin.

After delivery the infants were admitted to the nurs-

ery. The neonatologists were unaware of which treatment the mother had received. Blood cultures using antibiotic resin and a complete blood count were collected on admission. At the discretion of the neonatologist other studies included cerebrospinal fluid examination, chest x-ray film, and urinalysis. All infants then received intravenous ampicillin and amikacin. The neonatologist evaluated the infant between 12 and 48 hours of age and recorded the presence or absence of RDS, sepsis, pneumonia, or other complications that may have been present. RDS was diagnosed by respiratory distress necessitating oxygen therapy and a chest x-ray film consistent with hyaline membrane disease. Clinical sepsis was diagnosed by the neonatologist when the infant presented with hypothermia, hypotension, hyporeflexia, tachypnea, neutropenia, or leukocytosis with a left shift. Positive blood cultures were not considered essential for a diagnosis of sepsis, because the mother may have received antibiotics before delivery. Pneumonia was diagnosed by chest x-ray films and clinical examination. Intraventricular hemorrhage was diagnosed and graded by ultrasonographic examination. If cultures obtained from the infant were negative and there was no clinical suspicion of sepsis, use of antibiotics was discontinued at 72 hours. Infant antibiotic treatment was continued if the neonatologist suspected sepsis on the basis of the above criteria.

In a study performed at University Medical Center in 1987 the incidence of RDS in premature rupture of membranes before 34 weeks' estimated gestational age was 27%.[1] To show a 50% reduction in the incidence of RDS in the antibiotic group at the 95% confidence level, 60 patients were needed in each phase of the study, for a total of 120 participants. However, the study was stopped at 85 patients because of time constraints and the diminution of resources.

After the 85 patients had been delivered, statistical analysis was performed, using Student t test, χ^2 test, and Kaplan-Meier estimation when appropriate. After the analysis the study code was broken to determine the groups that received antibiotics or placebo.

Results

Eighty-five patients were randomized into a placebo group ($n=45$) and a treatment group ($n=40$). There were no significant differences between the two groups with respect to maternal age, race, gestational age by dates, gestational age by ultrasonography, estimated fetal weight by ultrasonography, prenatal care, and hours of premature rupture of membranes (Table I). There were no maternal deaths in either group.

Table II describes the infectious morbidity of the women in the study. Twenty-one patients in the placebo group also had positive cultures. Six of these patients had both gonorrhea and group B streptococcal organisms. Five had gonorrhea and 10 had group B streptococci. Of these 21 patients four were treated before delivery and chorioamnionitis did not develop. Chorioamnionitis developed in four patients during labor and these patients were treated. The other thirteen were not treated until after delivery.

Table I. Demographic data

	Placebo	*Antibiotic*
No.	45	40

Chorioamnionitis of placenta*	19 (75%)	12 (46%)	<0.05

*Histopathologic diagnosis.

The culture results were not available until 48 to 72 hours after collection. For this reason some patients were delivered before the diagnosis of the positive culture was available.

In the treatment group five patients had positive cultures for both gonorrhea and group B streptococci, three had gonorrhea only, and six had only group B streptococci organisms. Eleven of these 14 patients were delivered before the diagnosis was made. Chorioamnionitis developed in three and they were treated during labor, and three were diagnosed and treated before chorioamnionitis or labor developed. All these patients were retained in the study in their respective groups for the purpose of statistical analysis.

Chorioamnionitis, as defined above, was diagnosed in 16 patients in the placebo group compared with three patients in the antibiotic group. Endometritis-myometritis was found in 33% of the placebo group in comparison with 12% of the antibiotic group.

The interval from premature rupture of membranes to delivery (latency period) was significantly longer in the treated group (Table III). The mean latency period

Table III. Latency period*

Table IV. Indications and mode of delivery

	Placebo	*Antibiotic*
Spontaneous labor	23	26
Induced because of chorioamnionitis*	17	6
Induced because of suspected lung maturity	3	4
Fetal distress	2	2
Cesarean section	6	9
Forceps-vacuum	5	3
Spontaneous vaginal delivery	34	28

*$p < 0.05$.

was 8.25 days in the treatment group compared with 3.82 days in the placebo group. Seventy-five percent of the placebo group were delivered by day 3 after admission into the study. Conversely, 75% of the treatment group were not delivered until day 9 of admission into the study.

The indications for delivery were similar in the two groups (Table IV). The only significant difference was in the number of labors that were induced or augmented because of the suspicion of chorioamnionitis ($p < 0.05$).

The neonatal outcomes are listed in Table V. The infants born to mothers in the antibiotic group remained in utero longer and had significantly greater weight gain from time of premature rupture of membranes to delivery.

Table VI presents the neonatal morbidity data. Two infants in the placebo group had blood cultures positive for group B β-hemolytic streptococci within the first 48 hours of life. Clinical sepsis, as previously defined, was significantly more frequent in the placebo group ($p < 0.05$). A trend was present showing an increase in RDS in the placebo group. Intraventricular hemorrhage and hospital stay were significantly lower in the antibiotic group ($p < 0.05$).

Comment

Antibiotics were used in this study based on the assumption that premature rupture of membranes is initiated by an occult infection. If no treatment is started, this presumed infection may progress to frank chorioamnionitis and spontaneous labor. The purpose of our study was to arrest and cure any infection already present, not to prevent an infection. For this purpose mezlocillin, a broad-spectrum antibiotic that has proved to be effective when administered as a single-agent therapy for chorioamnionitis and endometritis-myometritis, was chosen.[17] Mezlocillin crosses the placenta and is found in cord blood and amniotic fluid at therapeutic levels, yet has no adverse effects on perinatal or postnatal development.

Patients with positive cultures were not removed from the study. Because it often takes longer than 48 hours to obtain a culture result, many patients with preterm premature rupture of membranes are delivered before the culture result is available. Antibiotic therapy may benefit such patients. Because patients with positive cultures represent a subset of all patients with premature rupture of membranes, they should be included in a study that investigates the benefits of initiating antibiotic therapy at the onset of premature rupture of membranes. As noted, four patients in the placebo group were diagnosed with positive cultures before the onset of labor or chorioamnionitis and were treated appropriately. It would be unethical to withhold antibiotics in such a situation. However, they remained

in the placebo group and their data were included in the statistical analysis at the end of the study. Three patients in the treatment group received appropriate treatment for positive cervical cultures before labor or chorioamnionitis developed.

The use of tocolysis and steroids was intentionally omitted so that the impact of the variable under study (antibiotics) would be elucidated. It was thought that once the role for antibiotics in premature rupture of membranes is established, then any advantage of adding tocolysis, or steroids, or both could be investigated at a later date. In this study mothers and infants with preterm premature rupture of membranes treated with antibiotics experienced better outcomes as measured by several parameters. The incidence of chorioamnionitis and endometritis-myometritis significantly decreased. Treated infants remained in utero twice as long and experienced three times the weight gain than that of the placebo group. Infants from the treatment group had significantly higher 1-minute Apgar scores and significantly decreased frequencies of intraventricular hemorrhage and clinically suspected sepsis. There was a trend toward less RDS. Furthermore, the treatment group infants had a decreased chance of prolonged hospitalization (>30 days).

Although the numbers do not permit adequate evaluation, it was noted that no difference in the perinatal death rate occurred between the two groups. The combined perinatal death rate was 70.6/1000 live births. In 1987 at the same institution before the initiation of this study, the perinatal death rate in cases of premature rupture of membranes before 34 weeks' gestational age was 129/1000 live births.[1] Perhaps the initiation of this study helped to decrease the premature rupture of membranes perinatal death rate in 1988. This study required close supervision of the mothers and meticulous antenatal testing of fetal well-being on a daily basis. The stringent supervision of patients with premature rupture of membranes required by the study design may have helped to decrease the perinatal death rate in both groups.

We conclude that the assumption of infection in preterm premature rupture of membranes in some patients is correct, and that since we are unable to clearly define which patients have occult infection, that antibiotic therapy appears to be justified. We found significant improvements in maternal and fetal outcomes. We did not discover any adverse effects from administering the antibiotics. However, it is understood that complications such as anaphylaxis or superinfection with opportunistic organisms can occur. The fact that we did not observe these complications could be explained by the small sample size.

Effect of tocolytic agents on fetal umbilical velocimetry

Jeffrey W. Wright, MD, Robert M. Patterson, MD, Louis E. Ridgway III, MD, and Michael D. Berkus, MD

San Antonio, Texas

In this prospective study, we sought to examine the changes in umbilical vascular resistance induced by tocolytic therapy. Umbilical artery velocimetry was performed in 46 patients with preterm labor before tocolysis and at 1 hour and 24 hours after tocolysis was initiated. Raw systolic/diastolic ratios were corrected for concomitant changes in fetal heart rate. Thirty patients received subcutaneous terbutaline and 16 were treated with intravenous magnesium. Systolic/diastolic ratios decreased in patients treated with terbutaline. This decline persisted after correction for increases in fetal heart rate. No significant changes in systolic/diastolic ratios were seen in patients treated with magnesium. We conclude that terbutaline may affect umbilical vascular resistance. Possible clinical implications of these findings are discussed. (AM J OBSTET GYNECOL 1990;163:748-50.)

Key words: Tocolytic, Doppler, umbilical velocimetry, terbutaline, magnesium

β-Sympathomimetic tocolytic drugs have profound effects on the maternal and fetal cardiovascular systems. Beta receptors are known to be present in the umbilical and uterine vasculature[1] and β-sympathomimetic tocolytics are known to cross the placenta.[2] It is possible that the vasodilatory action of β-sympathomimetics may affect vascular resistance in the umbilical circuit.

The recent development of fetal Doppler studies provides a noninvasive means of assessing umbilical vascular resistance. Brar et al.[3] used Doppler velocimetry to demonstrate a decline in umbilical vascular resistance in patients treated with ritodrine. However, these authors believed that increases in fetal heart rate may have confounded these results.

The purpose of this study was to assess the effect of terbutaline on umbilical vascular resistance as measured by systolic/diastolic ratio while controlling for the effect of an increase in fetal heart rate.

Material and methods

In this prospective study 46 patients who were seen in the labor and delivery suite with preterm labor were enrolled. Preterm labor was defined as gestational age between 25 and 34 weeks, and uterine contractions persisting after hydration, with cervical change. Patients with ruptured membranes, fetal congenital anomalies, previous tocolytic therapy, or complications associated with uteroplacental insufficiency were excluded. The choice of tocolytic agent was made by the individual patient's physician.

Thirty patients received terbutaline subcutaneously 0.25 mg every hour for 3 doses, every 3 hours for 8 doses, then 2.5 to 5 mg orally every 3 to 6 hours. Magnesium sulfate was given intravenously as a 4 gm loading dose followed by 2 to 3 gm/hr by infusion pump. After 8 to 12 hours of successful tocolysis with magnesium sulfate, patients were switched to oral magnesium oxide therapy, 200 to 400 mg every 4 hours.

A continuous-wave Doppler velocimeter (Angioscan III, Ultrasonix, Inc. North Yonkers, N.Y.) with a 4 MHz transducer was used to obtain all systolic/diastolic ratios. Patients were examined in the recumbent position with 15 to 30 degrees of lateral uterine displacement. Readings were taken between contractions in the absence of fetal breathing or fetal body movement. All studies were performed by one of the authors. The Doppler probe was positioned on the abdomen to obtain the best quality umbilical artery signals as recognized by the characteristic waveform and umbilical vein flow in the opposite direction. Peak systolic and lowest diastolic frequency shifts were measured with electronic calipers. Systolic/diastolic ratios were then calculated with five waveforms averaged to obtain each reading. Fetal heart rates were calculated by measuring the distance between waveform peaks with electronic calipers. Six patients in each group were initially studied before tocolysis was initiated, then at 30 minutes, 1 hour, 2 hours, 4 hours, 8 hours, 12 hours, 24 hours, and 48 hours after tocolysis was begun. This was done to estimate appropriate time intervals for study. On the basis of these preliminary results we studied the remaining

patients before tocolysis and at 1 hour and 24 hours after tocolysis was initiated.

Systolic/diastolic ratio data were analyzed in both raw form and after correction for fetal heart rate according to the method suggested by Mires et al.[4] For these systolic/diastolic ratio data and for fetal heart rate, analysis of variance for repeated measures was used to assess the effects of group and time. Duncan's new multiple range test was then performed for differences between individual means. The Statistical Analysis Systems statistical package was used for all analyses.

Results

Thirty patients received terbutaline and 16 received magnesium. The average gestational age was 30.8 ± 2.6 weeks and did not differ between groups. Four patients in the terbutaline group failed tocolysis after 1 hour. Thus 26 patients in the terbutaline group were examined at 24 hours. All patients in the magnesium group had labor successfully arrested for at least 24 hours.

Patients treated with terbutaline demonstrated a significant decrease in systolic/diastolic ratios ($p < 0.001$) (Table I). The majority of the decline in systolic/diastolic ratio occurred within 1 hour after the first dose of terbutaline. These differences were significant between baseline and 1-hour measurements, as well as between 1-hour and 24-hour measurements. The terbutaline group also exhibited a concomitant increase in fetal heart rate ($p < 0.001$) (Table II). The overall decline in systolic/diastolic ratio was still significant after correction for changes in fetal heart rate (Table III); however, the difference between the 1-hour and 24-hour measurements was no longer significant. The magnesium group exhibited no change in systolic/diastolic ratios (Tables I and III) or fetal heart rate (Table II). There were significant differences between the two groups for both raw and corrected systolic/diastolic ratios at 1 hour and 24 hours.

Comment

Our study shows a decline in umbilical artery systolic/diastolic ratios associated with use of terbutaline. This decline persisted after correction for fetal heart rate, which is the major known confounding variable. We found no similar change in the systolic/diastolic ratios of fetuses exposed to magnesium.

Brar et al.[3] recently found a significant decrease in

the uterine and umbilical artery systolic/diastolic ratios in patients treated with ritodrine for preterm labor. There was also a concomitant increase in the maternal and fetal heart rates, which the authors thought might have changed the systolic/diastolic ratios. They found no change in systolic/diastolic ratios or heart rates in patients treated with magnesium sulfate. In our study we corrected for the effects of fetal heart rate changes and confirmed that this decline in umbilical artery systolic/diastolic ratio is present in patients exposed to β-sympathomimetic.

Many patients and fetuses are exposed to tocolytic agents during pregnancy. Maternal side effects from these agents are well known and are sometimes serious. Conversely, fetal effects are less often considered. β-Sympathomimetic tocolytics have been associated with fetal cardiac dysrythmia, heart failure, myocardial ischemia, ventricular septal hypertrophy, and neonatal death.[5]

The possibility that β-sympathomimetic agents may affect fetal vascular resistance is physiologically sound. This study and that of Brar et al.[3] offer scientific data as confirmation. It may seem that vasodilation should promote better blood flow and oxygen delivery. However, Parisi and Walsh[6] have shown that vasodilation in the fetus may actually decrease placental blood flow by shunting blood to other vascular beds. It is possible that a decrease in vascular resistance caused by β-sympathomimetic tocolytics could be harmful to the fetus. Additionally, consideration also should be given to a patient's current drug therapy when interpreting diagnostic umbilical velocimetry measurements.

Does the umbilical artery systolic/diastolic ratio reflect flow or acidosis?

An umbilical artery Doppler study of fetal sheep

Joshua A. Copel, MD, Donald Schlafer, DVM, MS, PhD, Richard Wentworth, PhD, Kathy Belanger, PhD, Lois Kreitzer, MS, John C. Hobbins, MD, and Peter W. Nathanielsz, MD, PhD

New Haven, Connecticut, and Ithaca, New York

We studied four fetal sheep at 114 to 139 days' gestation to evaluate the effect of acute placental embolization on placental perfusion, fetal oxygenation and acid-base status, and the umbilical artery systolic/diastolic ratio. Studies were performed after maternal anesthesia was induced in an acute model, with serial umbilical artery embolizations performed at 20 to 30 minute intervals. Fetal umbilical flow, systolic/diastolic ratio, and arterial blood gas levels were followed up. One animal maintained a normal systolic/diastolic ratio despite a 50% drop in flow after the first injection and pH of 6.91, and died after the second injection. The remaining three animals showed significantly decreased flow after the third injection ($p < 0.02$), with no change in the systolic/diastolic ratio. The systolic/diastolic ratio increased significantly after the fourth injection ($p < 0.05$) when flow had dropped even further. Corresponding decreases in Po_2 and pH did not achieve statistical significance. The magnitude of all changes increased with subsequent embolizations. We conclude that in this model significant reductions in flow result in small increases in the systolic/diastolic ratio and that greater magnitude changes in the systolic/diastolic ratio appear only with severely diminished flow and Po_2, when acidosis develops. (Am J Obstet Gynecol 1990;163:751-6.)

Key words: Umbilical blood flow, Doppler ultrasonography, fetal flow, fetal sheep

The umbilical artery Doppler waveform has been proposed as a means to determine placental flow, function, and resistance.[1-4] Many growth-retarded fetuses show diminished end-diastolic frequency shifts.[5-10] In vitro, Doppler-derived flow measurements can be shown to correlate well with true volume flow.[11] The placental circulation is a complex system, and because of the tortuous nature of the umbilical arteries, as well as the broad spectra of the flow-velocity waveforms obtained from them, calculation of absolute flow in the umbilical arterial circulation is not yet feasible. This study was undertaken as part of an effort to match physiologic data in the catheterized fetal sheep to Doppler flow-velocity waveforms. The hypothesis to be tested was that acute reductions in umbilical arterial flow by placental embolization to increase placental resistance would lead to corresponding changes in the Doppler waveforms, as measured by the systolic/diastolic (S/D) ratio.

Material and methods

We studied four mixed breed fetal sheep at 114 to 139 days' gestation. After an overnight fast, the animals were brought to the operating suite and general endotracheal anesthesia was induced. Anesthesia was maintained with 2% halothane in oxygen. Laparotomy was performed and the pregnant horn was identified and opened. Through a left flank incision, the fetal common umbilical artery was identified, and a perivascular flow probe (Transonics Systems, Ithaca, N.Y.) was placed around it. Catheters were placed in the fetal femoral artery and vein. The femoral arterial catheter was advanced into the distal aorta to a point above the level of the common umbilical artery. After the fetus was replaced and the uterus was closed, the middle uterine artery feeding the pregnant horn was identified, and another perivascular flow probe was placed around it. The abdomen was then closed.

Blood gas data were obtained from an ABL2 blood gas machine (Radiometer, Copenhagen). Flow information was continuously collected on an IBM personal

computer with a commercially available data acquisition program (CODAS, Dataq Instruments, Akron, Ohio). Resistance was computed from the flow and arterial pressure information stored in this data base.

Abdominal ultrasonography was performed with an Advanced Technology Laboratories UltraMark 4 system (ADR Ultrasound, Bothell, Wash.), and the umbilical cord was identified. Doppler flow-velocity waveforms were obtained with a 3 MHz mechanical sector transducer and were recorded on videotape, with still images additionally obtained at the time fetal blood gas levels were collected, generally just before and 5 minutes after each embolic challenge. S/D ratios were measured whenever possible from the internal calipers of the Advanced Technology Laboratories machine, although some were not measured during the actual experiment. For those data, the videotape audio signal was fed through a Multigon 500A spectrum analyzer (Multigon, Mt. Vernon, N.Y.) and the S/D ratio was measured from that instrument's internal calipers. The S/D ratio was measured by placement of calipers at the peak systolic and end-diastolic frequencies of consecutive waves.

Average flow information was computed as the mean for 15-second intervals. The corresponding Doppler signals were taken from the same 15-second interval. At least three waves were analyzed, and the mean was calculated.

The experimental protocol consisted of baseline measurements of flow, Doppler waveforms, and fetal arterial blood gas levels after a stabilization period of at least 30 minutes. This was followed by an injection into the common umbilical artery of 10 ml dextran. Sequential embolizations were then performed by injection of 1.6 to 3.2×10^7 carbonized latex microspheres 15 μm in diameter through the catheter placed at the level of the common umbilical artery. Injections were given every 20 minutes, with an arterial blood gas measurement obtained 5 minutes later. The Doppler, resistance, and flow information were extracted for the same time as that of the blood gas sample.

Data were analyzed by use of paired Student t tests with statistical significance accepted at $p < 0.05$. S/D ratios were logarithmically transformed to impose a linear distribution.

Results

One of the sheep did not adequately recover a normal pH after surgery and remained at 6.91 through the baseline and control injection periods. The fetus died after the second embolic injection. It is interesting to note that the umbilical flow dropped by 50% after the first injection with no change in S/D ratio (Fig. 1).

The remaining three sheep were studied through six embolizations, receiving a mean total of 1.28×10^8 microspheres. Fig. 2 shows the sequential means of the S/D ratios, flows, and resistance values. The mean initial flow was 368 ml/min, the mean initial resistance was 209 dynes cm^{-2} ml min^{-1}, and the mean initial S/D ratio was 1.91. All were unchanged after the dextran control injection.

The first embolization dropped the flow to 354 ml/min, and the resistance rose to 220 dynes cm^{-2} ml min^{-1}. The S/D ratio was 1.8, unchanged from baseline. The second embolic injection decreased mean flow still further to 321 ml/min, whereas resistance rose to 252 dynes cm^{-2} ml min^{-1}. Mean S/D was 1.97.

The S/D ratio rose moderately after the third injection to 2.27, whereas the mean flow had dropped to 305 ml/min, and resistance rose to 252 dynes cm^{-2} ml min^{-1}. The flow was significantly reduced from baseline ($p < 0.02$), whereas the S/D ratio was not significantly elevated ($p = 0.27$). The resistance showed a trend, that was not significant ($p = 0.07$).

The fourth injection further compromised flow to 278 ml/min ($p < 0.001$ relative to baseline values), with resistance rising to 290 dynes cm^{-2} ml min^{-1} (still not achieving statistical significance). The S/D ratio rose to 2.55 ($p < 0.05$). The fifth and sixth injections had continuing effects on all three variables.

The mean initial pH was 7.16, which dropped minimally to 7.14 after the third embolization. After the fourth injection the mean pH was 7.11, not reaching significance ($p < 0.09$). The fifth injection lowered the pH still further to 7.05 ($p < 0.06$), whereas it reached 6.98 after the sixth injection ($p < 0.005$) (Fig. 3).

A look at each sheep individually further shows the pattern of responses to the embolizations. Fig. 4 shows the composite information for the three sheep that survived the entire protocol, comparing the S/D ratio with the umbilical flow data. The break points for the S/D ratios appear to be lagging behind the drops in flow.

In Fig. 5 the umbilical S/D ratio is compared with the fetal arterial pH. The break point more closely approximates that of the S/D ratio than was apparent from the flows.

Comment

The analysis of Doppler flow-velocity waveforms from the umbilical artery has been suggested to be beneficial in the identification of the growth-retarded fetus.[6, 7] Although whether it is better than ultrasonographic biometry remains in question, it may be a useful adjunct.[12] It has also been implied to be helpful to distinguish the true-positive from the false-positive contraction stress test, suggesting that fetal asphyxia or acidosis may influence the waveform shape.[13]

In this study we acutely stressed the fetoplacental circulation by repeatedly embolizing the common umbilical artery. After several challenges the umbilical flow began to drop, and was significantly reduced before there was any change in the S/D ratio. After one to two further injections we saw an increase in the S/D

ratio, approximately at the same time that the pH began to drop.

The most dramatic change we observed was in one fetus that remained acidotic after surgery, with pH 6.91. The umbilical artery S/D ratio was normal compared with the other lambs in this study and compared with Trudinger's standards[14] (1.62 versus Trudinger's mean 2.2). The first injection reduced umbilical flow by 50% with no change in S/D, whereas the fetus died shortly after the second injection. At 5 minutes after the second injection flow had dropped to 40% of baseline and the S/D rose to 2.35. Shortly after that the flow dropped to about 10% of baseline, at which point diastolic flow disappeared.

In the remaining three sheep, baseline S/D ratios were in the normal range as previously reported by Trudinger[14] and by Newnham.[15] Whereas the pH values appear low, the initial pH values were all within 2 SEMs as reported by Trudinger. Initial umbilical flows, and Po_2s were also within 2 SEMs reported by Trudinger. Thus the acute stresses of surgery did not appear to have altered these physiologic parameters at the start of the embolization series.

We observed significant drops in flow in all the sheep before obvious changes were apparent in the S/D ratio. The calculated placental resistance rose with each embolic injection. The reason for the lag in change of the S/D ratio after the change in flow is unclear. It may be a result of the time allowed for observation in this experimental design. But it may also reflect a true lack of sensitivity of the ratio to early, but nonetheless significant, reductions in flow. For example, an increase in spectral broadening or change in waveform shape may occur as flow initially drops. We did not attempt such measurements in the current study for a number of reasons. The simple S/D ratio will not change with either altered spectral broadening or changes in wave shape. The resistance index will also not be altered by either of these. The pulsatility index should reflect altered waveform shapes, but provides no information about spectral broadening. Because of the limitations of the equipment used for this set of experiments, we were unable to measure the pulsatility index. Spectral broadening is also not measurable by currently available equipment.

The ability of umbilical artery Doppler waveforms to change early in the course of adverse fetoplacental changes is critical to our understanding of the appropriate applications of this technology. For example, we previously observed on the lack of sensitivity of the S/D ratio to acute asphyxial insults in the fetus (unpublished observation).

In conclusion, we have found that the umbilical artery S/D ratio lagged behind true umbilical flow in alterations induced by acute placental embolization. We also showed that normal umbilical artery S/D ratios can

be found even in the presence of severely compromised flow and critical fetal acidosis. These preliminary data suggest that careful evaluation of chronic models of fetal and placental damage will be necessary to understand whether umbilical artery Doppler can be used to identify early chronic growth restriction in the fetus.

Infection and labor

VI. Prevalence, microbiology, and clinical significance of intraamniotic infection in twin gestations with preterm labor

Roberto Romero, MD, Fayek Shamma, MD, Cecilia Avila, MD, Carlos Jimenez, MD, Robert Callahan, BS, Jose Nores, MD, Moshe Mazor, MD, Carol A. Brekus, MSN, CNM, and John C. Hobbins, MD

New Haven, Connecticut

The purpose of this study was to establish the prevalence, microbiology, and outcome of microbial invasion of the amniotic cavity in twin gestation presenting with preterm labor and intact membranes. Amniocenteses were performed on both sacs of 46 women with twin gestations, preterm labor, and intact membranes. Indigo carmine was injected to ensure sampling of both amniotic sacs. Amniotic fluid was cultured for aerobic and anaerobic bacteria, *Mycoplasma hominis*, and *Ureaplasma urealyticum*. A positive amniotic fluid culture of at least one sac was noted in 10.8% (5/46) of patients admitted in preterm labor and in 11.9% (5/42) of women delivered of preterm neonates. Of the five patients with microbial invasion of the amniotic cavity, three had microorganisms isolated from both sacs. The presenting sac was involved in all cases, supporting an ascending route for microbial invasion of the amniotic cavity in twin gestation. Polymicrobial infection was found in three of the eight amniotic sacs with positive cultures. In two cases different organisms were isolated from each sac. All patients with positive amniotic fluid cultures were delivered of preterm infants within 48 hours of amniocentesis. Patients with positive amniotic fluid cultures presented with preterm labor at an earlier gestational age and with more advanced cervical dilatation than did women with negative amniotic fluid cultures. Clinical evidence of chorioamnionitis subsequently developed in two of five women with positive amniotic fluid cultures. The interval between amniocentesis and delivery was shorter in women with positive amniotic fluid cultures than in women with negative amniotic fluid cultures (median: 3.5 vs 168 hours, $p < 0.0001$). Infants born to women with microbial invasion of the amniotic cavity had a lower median birth weight and a higher incidence of respiratory distress syndrome than those born to women with negative amniotic fluid cultures (birth weight: 1085 vs 1975 gm, $p = 0.024$; respiratory distress syndrome: 37.5% vs 8.3%, $p = 0.04$). (Am J Obstet Gynecol 1990;163:757-61.)

Key words: Intraamniotic infection, twin gestation, chorioamnionitis, prematurity, preterm labor, parturition, labor

Although multiple gestation is an important risk factor for preterm labor and delivery,[1] the mechanisms responsible for preterm birth in this setting are poorly defined. Recently, the association between subclinical intrauterine infection and preterm labor has been recognized in singleton gestations (reviewed in reference 2). The contribution of intrauterine infection to the etiology of preterm labor in multiple gestation has not been established. The purpose of this study was to determine the prevalence of microbial invasion of the amniotic cavity in the setting of twin gestations.

Material and methods

Patient population. Patients admitted to Yale–New Haven Hospital with the diagnosis of twin gestation and preterm labor with intact membranes were offered amniocentesis for evaluation of the microbiologic status of the amniotic cavity. Patients were enrolled between Aug. 29, 1985, and Aug. 28, 1989. Preterm labor was defined as the presence of regular uterine contractions with a frequency of at least two every 10 minutes and documented cervical change in patients with a gestational age of < 34 weeks. Nitrazine, pooling, and ferning tests were performed in every case during a sterile speculum examination to exclude patients with rupture of membranes. Ritodrine, terbutaline, or magnesium sulfate was administered intravenously for tocolysis. Failure of tocolysis was diagnosed when cervical

dilatation progressed beyond 5 cm or delivery occurred.

Retrieval of amniotic fluid. Amniotic fluid was retrieved by transabdmonial amniocentesis performed under ultrasonographic guidance. Indigo carmine was injected after fluid was retrieved from the first sac to ensure sampling of both amniotic cavities.

Microbiologic studies. Amniotic fluid was transported to the laboratory in a capped plastic syringe immediately after collection. These conditions precluded air contact with the specimen. Plating occurred within 30 minutes of collection in all cases. Amniotic fluid was cultured for aerobic and anaerobic bacteria, as well as for *Mycoplasma* species, with techniques previously described in detail.[3] The results of the Gram stain examinations of amniotic fluid were shared with the clinicians. Patients with negative Gram stain examinations for bacteria were given tocolytic drugs. Patients with positive Gram stain examinations for bacteria were given parenteral antibiotics and allowed to labor. A positive Gram stain for bacteria was an indication for discontinuing tocolysis.

Criteria for the diagnosis of intraamniotic infection, neonatal sepsis, and respiratory distress syndrome. Intraamniotic infection was diagnosed by the presence of a positive amniotic fluid culture.[4] Clinical chorioamnionitis was defined according to the criteria proposed by Gibbs et al.[5] Neonatal sepsis was diagnosed by the presence of a positive culture of blood, urine, or cerebrospinal fluid. Respiratory distress syndrome (RDS) was defined as chest retractions, expiratory grunting, and a decrease in air entry that occurred shortly after birth and persisted for at least 6 hours, accompanied by a reticulogranular pattern in the chest film and without any evident cause of the respiratory distress.

Statistical analysis. Comparisons were performed with contingency tables and Fisher's exact test or χ^2 as appropriate. Amniocentesis to delivery interval and cervical dilatation between patients with positive and negative amniotic fluid cultures were compared with a Mann-Whitney U test.

Results

Amniotic fluid was retrieved from both sacs in 46 patients. A positive amniotic fluid culture of at least one sac was noted in 10.8% (5/46) of patients admitted with preterm labor. Of the 42 patients who went on to deliver preterm neonates, 11.9% (5/42) had a positive amniotic fluid culture. All five patients with a positive amniotic fluid culture had a preterm delivery. Of the five patients with positive amniotic fluid cultures, three had microorganisms isolated from both sacs. Table I displays the microbial isolates and quantitative microbiologic results for patients with a positive amniotic fluid culture.

Of the eight amniotic sacs with positive cultures, three had multiple microbial isolates. The Gram stain of amniotic fluid was positive for microorganisms in only one of eight colonized fluids. The presenting sac was involved in every case. There were no cases in which the nonpresenting sac was colonized without involvement of the presenting sac. In three patients the same microorganism was isloated from both sacs. The colony count and the number of microbial isolates were higher in the presenting than in the nonpresenting sac. The placentas of all twins with a positive amniotic fluid culture were dichorionic and diamniotic except for one case (monochorionic and diamniotic, case 3 in Table I). Clinical chorioamnionitis developed in two of the five women with positive amniotic fluid cultures and in none of the 42 patients with negative amniotic fluid cultures ($p = 0.009$). There were no cases of neonatal sepsis.

Table II displays gestational age and cervical dilatation on admission and the interval between amniocentesis and delivery, according to amniotic fluid culture results. Patients with positive amniotic fluid cultures presented with a more advanced cervical dilatation and progressed more rapidly to delivery than women with negative amniotic fluid cultures.

All patients with positive amniotic fluid cultures were delivered of preterm infants within 48 hours of amniocentesis. Fig. 1 displays the utilization of and response to tocolysis of all patients in this study. Of those with negative amniotic fluid cultures, four were delivered of term infants (>37 weeks). None of the neonates had confirmed sepsis. Infants born to women with positive amniotic fluid cultures had lower mean birth weights and a higher incidence of RDS than those born to women with negative amniotic fluid cultures (birth weight: median, 1085 gm; range, 540 to 2300 gm vs median, 1816 gm; (320 gm to 2480 gm); $p = 0.024$ (Mann-Whitney test); RDS: 37.5% (3/8) vs 8.3% (7/84); $p = 0.04$ (Fisher's exact test), respectively.

Comment

The association between intrauterine infection and preterm labor and delivery in singleton gestation has been the subject of intense investigation (reviewed in reference 2). The mean prevalence of positive amniotic fluid cultures in patients presenting with preterm labor and intact membranes is 13.6% (range, 0% to 25%).[6-17] Furthermore, in a recent study 21.6% of women who presented with preterm labor and intact membranes and went on to deliver a preterm neonate had a positive amniotic fluid culture.[4]

Although multiple gestation is a known risk factor for preterm delivery, the etiology of preterm birth in this setting is poorly understood. The traditional ex-

planation for the higher rate of preterm delivery in these gestations has been that uterine overdistention causes premature activation of the mechanisms responsible for the initiation of labor.[18] However, it is also possible that the premature cervical effacement and dilatation that occurs in multiple gestations favors an ascending infection and this, in turn, leads to preterm labor or preterm premature rupture of membranes (PROM).[19]

Our data indicate that microbial invasion of the amniotic cavity occurs in 11.9% of twin gestations presenting with preterm labor and delivering a preterm neonate (<37 weeks). This finding is in contrast to the 21.6% of positive amniotic fluid cultures observed in singleton gestations with preterm labor and delivery.[4] These data suggest that intraamniotic infection is a possible cause of preterm labor and delivery in twin gestation. However, the results of this study do not support the hypothesis that intraamniotic infection is responsible for the excessive rate of preterm delivery observed in twin gestations.

Intrauterine infection usually follows an ascending pathway from the lower genital tract. The observations made in this study support this view. First, in all cases of microbial invasion of the amniotic cavity, the presenting sac was involved. Second, when the same microorganism was found in both sacs, the inoculum size was larger in the presenting sac. Finally, no microbial

Table II. Clinical characteristics of patients with and without microbial invasion of the amniotic cavity

	Positive amniotic fluid culture	*Negative amniotic fluid culture*	*p Value*
Gestational age (wk) at presentation (mean ± SD)	29.2 ± 4.2	30.1 ± 4.2	NS
Cervical dilatation (cm) (mean and range)	4 (2-5)	2 (0-5)	0.047
Amniocentesis to delivery interval (hr) (mean and range)	3.5 (3-41)	168 (10–6 wk)	0.001

invasion was detected in the nonpresenting sac without involvement of the presenting sac.

The pathway of infection of the nonpresenting sac is not known. Infection of the second sac may be the result of further spread of decidual infection that has already involved the presenting sac or may be caused by transmembranous invasion from the presenting sac or by hematogenous spread. It is unclear whether the type of placentation (monochorionic or dichorionic) has a role in limiting transmembranous spread of infection. The spatial orientation of the sacs may have a role in determining the risk of infection of the second sac. If both sacs have sections adjacent to the cervix, the likelihood of infection is expected to be greater than if only one sac fills the entire lower uterine segment. The isolation of *Fusobacterium* species in two of our patients is of particular interest because these microorganisms are rarely a component of the normal vaginal flora. Vaginal cultures for these microorganisms were not performed in our patients, and thus we cannot comment on the source of this infection.

The contribution of intraamniotic infection to the morbidity and mortality of the preterm neonate is another issue that requires investigation. Neonates born to women with positive amniotic fluid cultures in singleton gestations are delivered at an earlier gestational age and have an excess of neonatal infectious morbidity, lower Apgar scores, and lower birth weights than those neonates born to women with negative amniotic fluid cultures.[4] In the current study neonates born to women with positive amniotic fluid cultures had a higher incidence of respiratory distress and lower mean birth weights than those born to women with negative amniotic fluid cultures. The extent to which respiratory distress is caused by aspiration of infected amniotic fluid and pneumonitis cannot be determined. The difficulties in the differential diagnosis between RDS and congenital pneumonia have been previously recognized.[20] Further studies are required to determine whether the excess incidence of respiratory complications in newborns born to women with positive amniotic fluid cultures is due to prematurity or to in utero microbial exposure.

The second twin generally has a greater incidence of complications.[21] Discordant intraamniotic infection may play a role in the differential morbidity and survival of twins. It might be argued that an intraamniotic infection in the presenting sac stimulates maturity in the presenting fetus while the second twin is not exposed to this stressing factor(s). This view may also be relevant to twin gestation complicated with preterm PROM.

It is impossible from this type of study to determine whether microbial invasion of the amniotic cavity is the cause of preterm labor or merely its consequence. Indeed, cervical dilatation as a result of labor could allow microorganisms from the lower genital tract to traverse intact membranes and gain access to the amniotic cavity. Alternatively, an ascending infection may signal the onset of labor. If intraamniotic infection is causally related to the initiation of parturition, our data would seem to suggest that infection of one sac is enough to trigger the onset of labor. Twin gestation offers a unique and naturally occurring model for the study of the mechanisms involved in the control of human parturition.

We gratefully acknowledge the assistance of Valerie W. Kraemer, MFA.

Superiority of the four-quadrant sum over the single-deepest-pocket technique in ultrasonographic identification of abnormal amniotic fluid volumes

Thomas R. Moore, MD
San Diego, California

Ultrasonographic estimation of amniotic fluid volume is an important adjunct to assessment of fetal well-being. However, no single method has emerged as most predictive. Many ultrasonographers use subjective or single-pocket guidelines in evaluation of amniotic fluid volume. We therefore assessed the ability of a maximum-vertical-pocket technique to identify patients with abnormal volumes of amniotic fluid. A total of 1168 patients was studied. Oligohydramnios (n = 76) was defined as an amniotic fluid index <5th percentile for gestational age (70 to 98 mm). Hydramnios (n = 51) was defined when the amniotic fluid index was >95th percentile (185 to 249 mm). The ability of the maximum-vertical-pocket technique to identify cases with oligohydramnios by amniotic fluid index was poor: sensitivity was 42% and positive predictive value was 51%. Fifty-eight percent of cases with oligohydramnios by amniotic fluid index had "normal" values according to the single-pocket technique. The correlation coefficient between amniotic fluid index and maximum vertical pocket was 0.51, R^2 = 24%. The correlation between the maximum vertical pocket and amniotic fluid index was somewhat better in cases of polyhydramnios (r = 0.79, R^2 = 62%), but the sensitivity, positive predictive value, and false-negative rates were high as in oligohydramnios. These data suggest that the maximum-vertical-pocket technique has adequate specificity but is a poor screening tool. The results demonstrate that use of gestation-specific norms for the amniotic fluid index identifies abnormal amniotic fluid volumes more efficiently than the single-pocket technique. (AM J OBSTET GYNECOL 1990;163:762-7.)

Key words: Oligohydramnios, amniotic fluid, polyhydramnios

Ultrasonographic estimation of amniotic fluid volume is an important adjunct to assessment of fetal well-being.[1, 2] However, no single method has emerged as most predictive. Subjective scales have been proposed,[3, 4] but these lack reproducibility. Somewhat arbitrarily defined "maximum-vertical-pocket depths" of amniotic fluid visualized on ultrasonographic scans have been used as a relative indication of amniotic fluid volume. Manning et al.[1] demonstrated that absence of a single pocket of amniotic fluid 1 cm in depth was associated with increased risk of fetal distress and perinatal mortality. Chamberlain et al.[5] used a "2 cm rule" to define marginal amniotic fluid (3% of 7582 high-risk patients). Intrauterine growth retardation and perinatal death were increased in these pregnancies. Similarly, a single pocket exceeding 8 cm (3% of their high-risk population) was predictive of increased rates of macrosomia.[6] However, Hoddick et al.[7] subsequently demonstrated that the "1 cm rule" has poor sensitivity in prediction of growth retardation. Bottoms et al.[8] noted that the maximum vertical pocket varied significantly during gestation and asserted that application of a single depth criterion was no better than subjective grading of amniotic fluid volume. To expand the sampling field, Phelan et at.[9] summed vertical fluid pockets in four quadrants of the uterus. Values of the amniotic fluid index <5 cm were predictive of high rates of meconium staining, fetal distress, and cesarean section.[10]

Most of the aforementioned studies have attempted to correlate one-dimensional scales of amniotic fluid depth to fetal outcome, yet none has established the ability of these schemes to predict accurately the amniotic fluid volume present. Recently we have demonstrated in the pregnant sheep that the amniotic fluid index has a close linear relationship to actual amniotic fluid volume (Volume = $-152+(4.2 \cdot$ amniotic fluid index), r = 0.94). In this setting, the amniotic fluid index was able to quantitate volume with 88% accuracy.[11] Moreover, our studies of normal amniotic fluid index

values in human pregnancy[12] have yielded a curve that is remarkably similar to that generated from indicator-dilution studies.[13]

The purpose of this investigation therefore was to compare the efficiency of single-value maximum-vertical-pocket cutoff values (2, 8 cm rules of Chamberlain[5, 6] with gestation-specific amniotic fluid index standards in detecting abnormalities in amniotic fluid volume.
